BMC Proceedings 2011, 5(Suppl 7):A1

Forest trees have unquestionably entered the genomic era. The updated version of the Populus genome, the recently released Eucalyptus grandis genome and the concerted efforts towards the generation of genome sequences for spruces (Picea sp.) and pines (Pinus sp.) by several groups worldwide, are fueling a multitude of inter-disciplinary studies and applications in sustainable forest production and conservation. Time now calls for the integration of scientific fields with an increased sense of urgency for delivery of effective biotechnologies.

The IUFRO (International Union of Forestry Research Organizations) Tree Biotechnology biannual conference has established a solid tradition for over 20 years as the official meeting of the IUFRO working group 2.04.06 – Molecular biology of forest trees. This conference has convened scientists and foresters interested in the genetics, genomics, molecular biology and physiology of forest trees, and the application of this knowledge to tree improvement and conservation. The Tree Biotechnology Conference has undoubtedly been the premiere international forum where the most cutting edge research in tree biotechnology developed both in academia and industry is presented. “From genomes to integration and delivery”, this was the theme chosen for the 2011 edition of the IUFRO Tree Biotechnology Conference, first time to be held in South America. Our intention was to promote a more integrated and applied dialogue on tree biotechnology and genomics, beyond the mainstream discussion of the fundamental advances on the genetic mechanisms that underlie tree phenotypes.

In nine scientific sessions some of the current advances of genomics applied to forest conservation, tree physiology, stress response, molecular breeding, in vitro and propagation technologies, wood development and genetically modified (GM) trees were highlighted. With 340 registered participants, the Conference brought to Brazil most of the world’s brain power in forest tree genomics and biotechnology. An outstanding team of international scientists shared their results and visions on the present and future of this fast moving area of forest science, while a brilliant group of young scientist and students delivered a very energetic and diverse collection of high-quality scientific presentations. Forty two countries were represented at the Conference with almost 100 different laboratories from tens of Universities, research institutions and private companies.

During the seven days of the Conference 26 invited lectures, 63 oral and 185 poster presentations were delivered, totaling 274 papers made available as extended abstracts into this BMC Proceedings supplement. The special workshop on the hot topic of “Genomic Selection in tree breeding” and the several reports on whole-genome studies, made this conference edition inaugurate a deliberate effort towards a better integration between the quantitative genomics, the “single-gene” and the system biology approaches to more efficiently unravel the complex relationships between genotypes and phenotypes in forest trees. A field trip to the forest plantations, nurseries and mill of VERACEL Cellulose was a definite highlight and a welcome break from the scientific sessions, providing an overview of some of the advances and challenges facing the translation of research into plantation forestry.

In closing this introductory statement, acknowledgements are due to the outstanding financial support provided by the competitive grants of the Brazilian Ministry of Science and Technology through the National Research Council (CNPq) and the Ministry of Education through its agency for graduate studies (CAPES). Major support was also provided by EMBRAPA (Brazilian Corporation of Agricultural Research), and VERACEL Cellulose, the host organizations, together with an exceptional suite of private sponsors. Besides the organizations that backed this conference and an active Scientific Committee involved in abstract review a number of people were involved in the organization and logistics. The conference would not have been possible without the valuable contributions of all these players. Given the rewarding feedback received after the Conference, the original goal of providing an exceptional mix of science, social activities and field exploration in a relaxed atmosphere was truly accomplished. The IUFRO Tree Biotechnology Conference 2011 made a significant contribution to advance the forest biotechnology research community one step ahead on the challenging task of moving from gene and genome discoveries to the delivery of valuable technologies into sustainable forestry.

S1. POPULATION GENOMICS, CONSERVATION AND ADAPTATION

II Missing heritability and missing Fst of candidate genes: why does gene variation differ from trait variation in trees?

BMC Proceedings 2011, 5(Suppl 7):S1

Molecular footprints of phenotypic variation are usually explored by two different approaches in trees. On the one hand, association genetics is...
seeking for statistical correlation between SNPs and traits owing to the significant heritability that is usually observed in progeny tests. On the other hand, detection of outlier Fst values of single SNPs has also been implemented to account for the very large differentiation of traits that are observed in provenance tests. The rationale of both approaches is based on the extensive within or between population genetic variability that has been widely recorded in fields tests. While the cataloguing of candidate genes has steadily increased in trees, so has the inventory of their diversity in natural or breeding populations. There is now a rapidly growing body of experimental results showing a very large discrepancy between the expectations of both approaches and the SNP variation that is monitored in candidate genes. Most association studies show that single SNPs explain usually less than 5% of the phenotypic variation of the trait, while Fst values are at best of the same value than neutral markers. In my presentation I will explore the reasons of the decoupling between trait and gene variation, by focusing on the multilocus structure of traits, as compared to the monolocus SNP information. Indeed, association studies and Fst outlier detection are essentially based on single locus approaches, while traits are multidimensional structures. There are at least three properties of multilocus structures that will be investigated: cumulativity, interactions and covariation of gene effects. I will show that cumulativity and interactions may explain the discrepancy in the case of association studies, while covariation of gene effects (at the between population level) explain the missing Fst of genes underlying adaptive traits. These conclusions are supported by experimental results, theoretical background and simulation predictions.

BMC Proceedings 2011, 5(Suppl 7):I2

Background: Forest trees exhibit striking adaptations to the environments in which they grow. A long history of quantitative genetic experimentation has established the genetic basis for many traits, which are likely adaptive since many of them are also correlated with environmental heterogeneity. The genes underlying these traits, however, have largely remained elusive. Recent applications of high-throughput sequencing and genotyping technologies to natural populations of forest
trees have identified several promising candidates for genes underlying complex and adaptive traits (reviewed by [1]). The diversity of analytical approaches employed in those studies, however, begs the question of the generality of reported results. Here, I exploited the diversity of analytical approaches used previously to identify genes underlying adaptive traits for two conifer species to assess the logical consistency among results generated from different conceptual frameworks.

**Materials and methods:** Data sets comprised of genotyped single nucleotide polymorphisms (SNPs) were gathered for two North American conifers (Fig. 1): loblolly pine (*Pinus taeda* L.) and coastal Douglas-fir (*Pseudotsuga menziesii* (Mirb.) Franco var. *menziesii*). These data sets were generated through resequencing of diversity panels (*n* = 18-24 megagametophytes) for a sample of expressed sequence tag (EST) unigenes (*n* = 7,535) and cold-hardiness related candidate genes (*n* = 121), respectively. Genotyping was performed using Illumina’s Infinium (loblolly pine) or GoldenGate (coastal Douglas-fir) array technologies. For each data set, associations to phenotypes and environmental variables were gathered from the literature or performed as described elsewhere.

---

**Figure 2** (abstract 12) An example of logical consistency for loblolly pine between genes associated to phenotypes or environmental variables and gene categories that have average deviations from neutrality consistent with positive or negative selection. Error bars give 99% bootstrap confidence intervals for the direction of selection statistic (DoS), with yellow bars having confidence intervals excluding zero. Lines give average Tajima’s *D* for nonsynonymous (blue) and synonymous sites (green), as well as the proportion of genes associated to at least one phenotype (red). Shaded areas give null distributions (99% quantiles) generated via permutations of genes among categories (*n* = 10,000 permutations). All lines, including those forming the null distributions, were smoothed using lowess smoothing.
Tracing the history of South-American neotropical savannas and seasonally dry forests evidences from comparative phylogeography

Background: The Neotropical Seasonally Dry Forests (SDF) are tree-dominated ecosystems that occur in disjunct areas of fertile soils throughout the Neotropics. The hypothesis that the vicariance of a formerly continuous seasonal woodland formation, which may have reached its maximum extension during a dry-cool period 18,000–12,000 BP (the LGM), the Pleistocene Arc Hypothesis, has been raised to explain the disjunct distribution [1]. Alternatively, based on the distribution of contemporary SDF species in Amazonia Forest and palynological data, recent post-glacial SDF may have evolved in the Amazon Basin during the Pleistocene, with rain forest and montane taxa largely confined to gallery forest. In addition, a number of studies based on the fossil pollen record now available show that during the early Holocene period (until ca. 6000-5000 14C BP), the climate was drier in most of the South American savannas and distribution of savanna-like vegetation in Central and Southeast Brazil was more extensive in early compared with the late Holocene [3-5]. In southeastern Brazil, the current vegetation exist in the region only in the latest Holocene period (since 970 or 600 BP for some regions) under the current wet climatic conditions, with an annual dry season of about 4 months. Hence, the fossil record shows that savanna expansion in the Quaternary, especially in southeastern Brazil was characterized mainly by herbaceous and grass savanna which were favored by the drier and highly seasonal climate. It is possible that arboreal savanna taxa became restricted to sites with moist climatic conditions, which served as refugia. We are interested in these hypotheses using the genus Tabebuia as model group. We have chosen five species based on the pattern of geographical distribution: T. aurea and T. ochracea, from savanna vegetation (cerrado sensu stricto), T. impetiginosa, T. roseo-alba from SDF, T. serratifolia, widely distributed in Mata Atlantica, SDF, riparian forests and Amazonia. Here, we present the results based on the phylogeography of T. impetiginosa.

Methods: We first generated a phylogenetic hypothesis based on sequences from three non-coding regions of cpDNA and ITS from nuclear rDNA. At least 16 individuals from 14 populations were sampled and sequenced for three chloroplast intergenic spacers (1635bp). We also sequenced individuals of T. ochracea, T. chrysanta, T. chrysotricha and Cybstax antisyphilitica, as outgroups to estimate coalescence time and better understand the biogeographical history of T. impetiginosa. Time to most recent common ancestor was estimated based on coalescent analysis implemented in BEAST 1.4.7 software [6]. For distribution modeling, we used 77 records of T. impetiginosa and four climatic variables representing annual rainfall and variability, average temperature of the warmest and coldest months) derived from four different coupled Atmospheric-Oceanic Global Circulation Models (AOGCM): CCSM3, CSIRO, HADCM3 and ECHAM. Five different niche models were used: the BIOCLIM , Euclidean Distances (EUL) Mahalanabis Distances (MAHAL), Genetic Algorithm for Rule Set Production (GARP), and Maximum Entropy (MAXENT). For each of the NM, a total of 750 different models were generated, using distinct combinations of dataset partition and variable selection. The paleoclimate scenarios were based on the GCM Genesis 2 [7].

Results and discussion: We have no evidences of a recent connection of the SDF in the LGM. Coalescent analyses showed that T. impetiginosa populations probably originated at ~7 Myr BP, but populations started to diverge only ~2 Myr BP, with the divergence of two major clades, one that comprises the populations from the East and West boundaries of Cerrado Biome, and the other that corresponds to the forests from Central, West and Northeast Brazil. Major divergences in this last clade coincide with the Quaternary glaciations. Our results strongly support that the disjunct distribution of T. impetiginosa may be derived from vicariance and that
long distance gene flow is unlikely, since we found a deep genealogy with alopatic lineages and a remarkable differentiation among populations (AMOVA, Arlequin v. 3.11) [8]. Paleodistribution modeling together with coalescent simulation showed no connection among SDFs in the LGM. Thus, glaciations may have most likely caused population divergence and differentiation due to retreat and range shift of an ancient forest widely distributed throughout the Central, Southwest and Northeast Brazil. Hence, we hypothesize that the isolation of an ancient forest due to a global cooling and drying during the glaciations of Pliocene/Pleistocene is responsible for the disjunct distribution of the SDF and T. impetiginosa. Our results also indicated that the last glaciation in Pleistocene were most likely responsible for local differentiation because lineage diversification within localities coincides with ~ 100 kya BP but without important demographic effects because populations showed a constant effective population size and no exponential growth or shrink. In conclusion, the range shift of T. impetiginosa toward the Northwest and the lack of a connection among SDFs in the LGM support the hypothesis of a kind of SDF in Amazonian Basin during Pleistocene glaciations but did not support the Pleistocenic Arc Hypothesis.

Acknowledgments: Phylogeography analysis of Cerrado tree species have been continuously supported by competitive grants of CNPq to RGc. Our research program integrating macroecology and molecular ecology has been continuously supported by grants to the research network GENPAC (Geographical Genetics and Regional Planning for natural resources in Brazilian Cerrado) supported by CNPq/MCT/CAPES (project # 564717/2010-0 and 563624/2010-8).

S2. LINKAGE AND ASSOCIATION MAPPING

14 Genomics-based breeding in forest trees: are we there yet?
David Neale
University of California-Davis, USA
E-mail: DBNeale@ucdavis.edu
BMC Proceedings 2011, 5(Suppl 7):14

Efforts to develop genetic marker based approaches to breeding forest trees began in the late 1980s. Approaches based on first generation of markers, allozymes, were not feasible due to the very limited number of markers (<50). The first DNA-based markers, RFLPs, brought more hope as moderately dense genetic maps could be constructed to scan the genome and map quantitative trait loci (QTLs). This approach was quite effective toward mapping QTLs in many forest tree species but the approach could not be brought to application in tree breeding due to low levels of linkage disequilibrium (LD) in forest tree breeding populations and recombination between flowering markers and QTLs with each generation. The next generation of DNA markers based on the polymerase chain reaction (PCR), RAPD, AFLP and SSR, did not solve the LD and recombination problem, even though more markers were available and throughput increased.

The situation began to change in the early 2000s with the availability of automated DNA sequencing technology and single nucleotide polymorphism (SNP) genetic markers. Now association studies could be performed where SNPs within candidate genes controlling complex traits could be identified and thus “solving” or minimizing the LD and recombination limitation. This approach to complex trait dissection has been widely applied in forest trees and the early approach of QTL mapping in segregating populations has been mostly abandoned. The association genetic approach has been used to find candidate gene SNPs associated to a broad array of quantitative traits of interest (wood properties, growth, abiotic stresses and disease resistance). However, like QTL mapping before, individual SNP x trait associations only account for a small proportion of the variation (generally less than 2-3% of the total phenotypic variance) and the total variation explained by all markers is generally less than 50%. In human genetics, this situation is called the “missing heritability” and there has been great debate over whether this problem can ever be solved in complex trait dissection in humans. In a few agricultural systems however, notably dairy cattle, researchers are now accounting for nearly all the heritable variation.

Efforts to realize genomics-based breeding in conifer tree improvement in the US have culminated under a collaborative research project funded by the USDA. The Conifer Translational Genomics Network Coordinated Agricultural Project (CtnG CAP) has successfully brought genomics-based breeding to application in the four major cooperative forest tree breeding programs in the US. The project has completed the basic research on allele discovery of economic traits in conifers, conducted the translational research, and provided education and training to tree breeders to realize this goal during the four-year project period (2007 to 2011). Genomics-based breeding can now be applied to the production of over 1.3 billion loblolly pine, slash pine and Douglas-fir seedlings planted annually in the US.

The CTGN CAP obtained high-density single nucleotide polymorphic (SNP) genotypes (over 7000 SNPs) on nearly 10,000 loblolly pine, slash pine, and Douglas-fir trees from the breeding cooperatives. These data were used to estimate molecular breeding values that can now be used to make selections as an alternative to breeding values based on mature traits that can take many years to the time of evaluation and can be expensive to measure in field tests. The CTGN CAP was the first to apply the advanced Illumina Infinium SNP-genotyping technology that is now being used in the breeding of most major crops such as corn, wheat, tomato, potato, and many more.

The CTGN CAP culminates a long-term investment by the USDA in this team of researchers and their work on the technological advancement of tree breeding in the US. USDA’s efforts began more than 20 years ago with funding of a series of grants under the National Research Initiative Plant Genome Program and continued under the CSREES IAFS and AFRI programs. Recently, NIFA has awarded a grant to members of this team to conduct full genome sequencing in loblolly pine, sugar pine, and Douglas-fir. The full genome sequence will soon allow tree breeders to practice genomics-based breeding using genetic variation from the entire genome (genomic selection), and thus minimizing or even eliminating the missing heritability problem in forest trees. The partnership between USDA research programs and this team of researchers has resulted in a modernization of tree breeding technology in the US that will secure US competitiveness in the production of forest products.

15 Identification of genes and alleles influencing wood development in Eucalyptus
Simon Southerton*, Shannon Dillon, Bala Thumma
CSIRO Plant Industry, Australia
E-mail: simon.southerton@csiro.au
BMC Proceedings 2011, 5(Suppl 7):15

The goal of many forest tree breeding programs is to increase the quantity and quality of wood products from plantations. Due to their outcrossing breeding systems, long generation times and relatively short history of domestication, breeding populations of most forest trees
closely resemble the wild state. Consequently, vast stores of genetic variation are available for selection. Because wood traits are under polygenetic control (quantitative), genetic improvement will rely on selection of multiple alleles, each of relatively small individual effect.

Marker-assisted selection may enhance tree breeding programs by enabling informed selection of parents for crossing; fixing desirable alleles in the homozygous state; increasing selection intensity through screening large numbers of individuals; enabling early selection in seedlings and by reducing phenotyping costs. The low linkage disequilibrium found in most forest trees makes them ideally suited to candidate gene-based association mapping approaches for marker discovery. This approach seeks to find alleles which affect phenotype and that remain linked to the trait across populations and over many generations. This methodology is well suited to tree breeding programs which aim to maintain a broad genetic base i.e. programs with a large number of families.

We are using association studies to identify genes and allelic variation that influences wood fibre properties in Eucalyptus nitens. Candidate genes are being selected on the basis of their known involvement in cell wall synthesis pathways expected to impact wood traits. Single nucleotide polymorphisms (SNPs) are identified in candidate genes by sequencing in a number of unrelated individuals. Selected SNPs are being genotyped across E. nitens populations that have been extensively phenotyped for wood properties including cellulose and lignin content, pulp yield, MFA, and density. Several SNPs significantly associated with wood properties have been identified and subsequently validated in other provenance or mapping populations growing in different environments. Selected SNPs are being investigated further to determine whether or not the SNP is the causative polymorphism and how the polymorphism influences the trait. DNA markers identified in this research may be useful to complement existing index selection strategies in E. nitens breeding programs. Strategies for exploiting SNPs for marker-assisted selection in seedling-based breeding programs will be discussed.

16 Gene mapping in white spruce (P. glauca): QTL and association studies integrating population and expression data

BMC Proceedings 2011, 5(Suppl 7):6

Background: Connecting phenotype with genotype is the basis for developing forest genetic applications such as marker assisted selection (MAS). Quantitative Trait Locus (QTL) mapping and genetic association mapping (or linkage disequilibrium (LD) are two major approaches to find genes that control phenotypes of interest in forest trees. Quantitative trait loci (QTL) and association mapping experiments in white spruce (Picea glauca [Moench] Voss) aimed to identify genes linked to or associated with growth, adaptation, and wood property traits.

Gene mapping in conifer trees presents us with specific challenges, including very large genome sizes, low level of linkage disequilibrium, and large effective size in breeding populations. Therefore, association mapping experiments have relied on testing candidate gene targets rather than whole-genome association scans. We have exploited different approaches to utilize gene expression and SNP outlier data to identify candidate genes, to help explain the findings of gene mapping experiments and provide a broader understanding of observed phenotypic variations.

Results: Growth and phenology: The genomic architecture of bud phenology and height growth was investigated by assessing QTLs across pedigrees, years, and environments (1). A total of 11 distinct QTLs for bud flush, 13 for bud set, and 10 for height growth were localized on a linkage map highly-enriched in gene markers. Nearly 50% of the QTLs were stable across environments and/or years and 20% were replicated between populations. The proportion of phenotypic variance explained by QTLs ranged from 3% to 22.2%, and QTLs accounted for up to 70% of trait variance. These outcomes were integrated with findings from studies aimed identifying local adaptation genes and gene expression associated with bud formation.

A genome-wide scan of 534 SNPs localized in 345 expressed genes was used to detect genes potentially linked to local adaptation (2). We identified 55% of genes as outliers with FST at the 95% confidence level, and 14% of genes as candidates for local adaptation with a Bayesian method. The list of candidate genes and outliers includes sequences which co-localized with the QTLs for bud phenology.

A bud set roadmap was constructed by comprehensive microarray and qRT-PCR analysis of dormancy transition in bud, stem, needle, and root tissues over a time course, under short and long days (3). Tissue expression profiles were used to identify genes expressed only or preferentially in developing buds, which we hypothesize to play a more prominent role in bud formation. A core group of genes likely involved in the initiation of bud formation included about 100 of the bud-prominent genes and several sequences encoding potential regulatory proteins. Several of the bud set roadmap genes including bud-prominent genes co-localized with QTLs for the time of bud set.

Wood properties: Wood physical traits were assessed using SilviScan technology in a population of 1700 trees comprising 215 open-pollinated families. In a pilot study, we tested for associations between single nucleotide polymorphisms (SNP) in 550 candidate genes and wood traits in several populations encoding potential regulatory proteins. Several of the phenotypic variance explained reached up to 11% with approaches combining several SNPs. Most association studies of wood properties have tested candidate genes that are highly expressed in secondary xylem, hypothesizing that genes that are preferentially or strongly expressed during wood formation are more likely to control wood properties. However, this hypothesis had not been tested. The genotyped sequences included genes with diverse expression profiles. Their transcript accumulation profiles were determined in trees grown under controlled conditions with a large-scale custom oligonucleotide microarray representing 25,094 different spruce genes. Of the 550 genes tested for association, 29% accumulated preferentially in secondary xylem compared to both secondary phloem and needles, but as many genes (29%) were phloem preferential. Xylem-preferential RNA accumulation was found for 10 of the 13 genes harbouring SNPs significantly associated. Our findings confirm that expression data were relevant for selecting candidate genes but not all of the genes containing significant SNPs were xylem preferential.

Transcript accumulation was also studied in secondary xylem of trees from the provenance-progeny trial, to further characterize the genes containing SNPs significantly associated with wood traits. In some cases, significantly different transcript levels were found among the different SNP genotypes. Xylem-preferential RNA accumulation was shown for the majority of these genes, which indicates that. Our results suggest that differential expression may be associated with SNP genotypes.

Large-scale genotyping: A meta-analysis was used to integrate data from multiple experiments in order to identify and assign priorities to approximately 5000 candidate genes for association mapping experiments. The candidate gene selection considered the above gene expression data, findings from transcriptomic investigations of gene regulation, studies investigating transcriptional variation within mapping populations trees, and outlier data related to local adaptation. A large-scale genotyping chip was developed and data were obtained for 7000 SNPs from nearly 2500 genes.

Conclusions: This report describes QTL mapping and genetic association mapping results. We have illustrated ways in which gene expression and SNP genotyping data may be of value in these approaches, whether they are used to select candidate genes or to characterize the physiological processes underlying marker-trait associations.

BMC Proceedings 2011, 5(Suppl 7):7

Background: Growing demand for food and fiber, and a rapidly changing climate will require that plant breeders accelerate the improvement of germplasm adapted to new sources of biotic and abiotic stress. In trees, the threat from climate change is more evident and the solutions more challenging than in any other plant species, due to the complexity and cost of breeding programs, and the long breeding cycles. Therefore, the discovery of genetic polymorphism that can be exploited for early selection of better adapted and productive individuals is essential. Quantitative trait loci (QTL) analysis provided an initial glimpse at the architecture of complex traits, but limited transferability across populations and resolution hampered the adoption of markers in tree breeding programs. Recently, association studies have become the method of choice for detection of markers implicated in trait variation, because of higher resolution, population transferability and allelic diversity captured relative to the QTL approach. However, in tree species, association studies have been largely constrained to sampling the genetic diversity in a limited fraction of the genome, and in small populations. Evidence from genome-wide association studies (GWAS) in humans and advanced crops clearly show that large populations, and the sampling of regulatory variants and rare alleles is critical to dissect the genetic control of complex traits for marker-assisted breeding (MAB). As the limitations of QTL and GWAS approaches become evident, “hybrid” intermediate strategies that combine the advantages of both methods have emerged. Notably, genomic selection has become an alternative to MAB. Genomic selection (GS), which relies on developing genome-wide marker-based models that predict the genetic value of progeny, will be particularly valuable for early selection in tree breeding programs. However, the implications of GS may also be highly valuable to identify mating designs that generate progeny with optimal allelic combinations for superior growth and wood properties, and adaptive capabilities.

Methods: To address limitation of recent association studies in forest tree species we have adopted an approach that combines targeted sequence-capture followed by high-throughput sequencing, to genotype eastern cottonwood (Populus deltoides) and loblolly pine (Pinus taeda) populations. To identify genetic polymorphisms that regulate biomass productivity, wood quality, and disease resistance, we have optimized methods of sequence-capture targeted regions of the genome for unbiased, high-throughput and low cost recovery of coding and regulatory sequences. This establishes the foundation for GWAS in both species, addressing a critical limitation of these studies in tree genomes – i.e. sampling of regulatory variants and rare alleles. While the work described above resolves part of the challenges of association studies, the use of GWAS will be most useful for discovery of genes to be targeted for genetic modification, rather than MAB. This is the case because the fraction of the total genetic variation explained by association studies is likely to remain small, considering the limitations of the existing populations. In an effort to implement marker-based breeding, we recently completed the first assessment of the utility of GS in an experimental population of loblolly pine, where we explore the contribution of factors such as age of model estimation and site location on the accuracy of prediction models. Furthermore, the incorporation of non-additive effects to prediction models has been evaluated for improvement of their accuracy.

Results and conclusions: Two association studies are currently underway, in loblolly pine and Populus deltoides, where a large fraction of the coding and regulatory sequences of their genomes are being re-sequenced for SNP detection. Existing results from sequence capture suggest that the majority of targeted regions can be effectively captured, even in genomes of very high complexity, such as that of loblolly pine. In parallel we have now verified the suitability of applying genomic selection to a breeding population of loblolly pine. Estimates generated for prediction models developed for this population indicate that accuracies that are comparable to traditional phenotypic selection can be obtained. Therefore, considering the significant reduction in the breeding cycle length due to early identification of elite genotypes, the increase in efficiency per unit of time in the selection response of genomic selection is almost twice as high compared to traditional breeding. By combining GS with advanced methods of vegetative propagation, breeding and seedling production, a breeding cycle can be reduced from decades to less than 5 years. While early selection of superior genotypes is an obvious application of GS to tree improvement programs, prediction models can be utilized to guide the mating design of future breeding cycles to favor stacking of favorable alleles over multiple generations. Towards this end, we have initiated crosses aimed at generating families that are predicted to have exceptional adaption, as well as biomass growth and quality properties for bioenergy, pulp and paper and timber production.

18 Genomic selection in loblolly pine - from lab to field

Fikret Isik1, Ross Whetten, Jaime Zapata-Valenzuela, Funda Ogun, Steven McLeod
Cooperative Tree Improvement Program, North Carolina State University, Raleigh, USA. E-mail: fisik@ncsu.edu

BMC Proceedings 2011, 5(Suppl 7):8

Background: Tree breeding is logistically complex and expensive, and breeders have long sought to use molecular markers to accelerate breeding. A candidate gene approach based on testing for association between the presence of DNA sequence variation in or near candidate genes, and phenotypic variation in a population has long been explored [1,2]. However, using candidate gene approach (QTLs) has not been successful in breeding [3,4]. QTL-trait associations detected in one genetic background are often not observed in other families, because of recombination of genes during the segregation and low levels of linkage disequilibrium in the population. A new technology called genomic selection (GS) is revolutionizing dairy cattle breeding. In GS, marker effects are first estimated in a large training population (>500) with both phenotypic and genotypic data. Subsequently, estimated marker effects are used to predict breeding values in validation populations for which marker genotypes but not phenotypes are available [4]. Several dairy cattle breeding companies now routinely use GS to select and market bulls. The success of GS in cattle breeding is largely based on bovine genome sequencing and discovery of thousands of SNP markers. GS application, if successful, will have a great impact on forest tree breeding because of their complex and logistically difficult breeding programs. Although, there have been several simulation studies examining the effective population size, linkage disequilibrium, and heritability on the predicted accuracy of
GS in tree breeding [5], GS has not yet been demonstrated for forest trees using empirical markers data, mainly due to lack of sufficient dense markers.

Methods: Biallelic SNP markers provided by the CTGN project (http://denдроме.ucdavis.edu/ctgn/) were used for genotyping. A population of 149 cloned full-sib offspring of lobolly pine (Pinus taeda L.) was phenotyped. Fitting 3406 informative SNP markers simultaneously, we estimated genome-wide breeding values and compared them with breeding values based on pedigree model. Variances explained by the marker additive and dominant effects were observed.

Results: The accuracy of the genomic estimated breeding values ranged from 0.30 to 0.83 for growth and wood quality traits. Lignin and cellulose content had great accuracy values from GS compared to growth traits. The accuracies were comparable with breeding values that were calculated based on the traditional pedigree model. If we take into account time needed to complete progeny testing, GS would be more efficient than classical progeny testing for some traits. The marker additive effects explained 18% and 23% for lignin and cellulose, respectively. Variances could not be determined for height and volume, because the Gibbs sampler failed to converge, even after five million iterations. We speculate that observed accuracies in this study trace familial linkage rather than historical LD with trait loci, because of small population size and relatively dense markers. The markers are sampling the haplotypes and thus constructing the pedigrees rather than explaining phenotypic variance. Nevertheless, the results are promising, and we expect that with decreases in genotyping cost, GS has a potential to fundamentally change tree breeding in the near future.

Challenges of GS applications in tree breeding: Despite promising results from some early work based on empirical data, there are some challenges to overcome to routinely use GS in tree breeding. Conifers have genome size with a range between 18,000 and 40,000 Mbp [6]. Their populations have low levels of LD which decays rapidly. LD in loblolly pine decays to less than r²=0.25 within 2000 bp [7]. Low LD is due to genetic recombination over the evolutionary history of the species and causes inconsistency of QTL-marker association. Large genome size and historically low LD require large numbers of dense markers to explain a considerable amount of phenotypic variation in complex traits. Another challenge is the lack of genetic maps in forest trees. With a few exceptions, the genomes of forest trees have not been sequenced, and thus precise locations of SNP markers are lacking, which hinders the use of haplotypes. Using haplotypes reduces the dimensions of the data and thus requires much smaller computing resources to analyze. More importantly, with haplotypes, larger variation between trees can be obtained using allelic combinations, although larger training populations are required to adequately sample the effects of all the haplotypes. High marker genotyping cost is the major obstacle in applications of GS in forest trees. More cost efficient genotyping technologies, such as genotyping-by-sequencing and restriction digestion, are being explored to reduce cost of markers. On the other hand, advances in computer power have made it possible to analyze large amount of complex data, but bioinformatics challenges still remain to analyze sequence data and SNP marker calling.

Further research is needed in development of training models and calibration of the prediction model. The number of generations that statistical models can be used before losing accuracy remains to be determined in forest trees. Another question is the validity of models across different populations. In cattle breeding, lower accuracies of GS for dairy versus beef cattle remains a challenge. For some tree species, GxE interaction could be an issue to be addressed; observed marker-trait association observed in one population may not hold in another environment.

Conclusions: We are currently working on construction of realized genomic relationship matrix based on SNP markers to use in predictions of breeding values. This method provides flexibility in terms of fitting common environmental effects in mixed models. We expect that decreases in marker genotyping costs will make GS in pine breeding feasible. Our group is also working on pilot projects with forestry companies in the southern US, and plans are underway to revise breeding strategies to incorporate genomic selection.

BMC Proceedings 2011; 5(Suppl 7):i9

Phenolic metabolites that contain salicylic acid (SA)-like moieties are major non-structural constituents in Populus leaves, shoots and roots. These so-called phenolic glycosides (PGs) are taxonomically limited to the Salicaceae, where they are known to mitigate insect and animal herbivory. SA itself is an important signaling molecule in plant defense and abiotic stress responses, and is derived from the isochorismate or phenylpropanoid pathways, depending on the species [1,2]. Hyper-accumulation of SA reduces growth in Arabidopsis[3], while high levels of PG have been associated with reduced growth in Populus[4]. Although the common PGs, saligenin, salicortin, and their derivatives contain a salicyl moiety, a direct metabolic relationship between PG and SA in Populus has not been shown. We have therefore been using stable isotope tracers, cell culture feeding, functional genomics and transgenic perturbation to probe the relationship between SA, PG and growth in Populus. Stable isotope incorporation confirmed a hydroxycinnamate-benzoate origin of the salicyl moiety of PGs, and provided the first empirical evidence that the bioactive hydroxycyclohexenone moiety of salicortin is also a phenylpropanoid derivative [5]. Therefore it is unlikely that PG biosynthesis involves the salicylic acid pathway. To further address any possible involvement of the isochorismate pathway in PG biosynthesis, isochorismate synthase (ICS) was characterized. ICS is present as a single-gene in most sequenced plant genomes, but is duplicated in Arabidopsis. In Arabidopsis, chloroamine-derived SA is the obligatory route for defense signaling, mediated by AtICS7 in response to various biotic and abiotic cues. In contrast, the single-copy Populus ICS is not stress-inducible, and is involved in biosynthesis of phyloquinone for photosynthetic electron transport [2]. We found no evidence of ICS involvement in SA or PG biosynthesis in transgenic Populus, pointing to lineage-specific evolution of the ICS-derived SA pathway in Arabidopsis. We transformed Populus with the bacterial genes for the biosynthesis and degradation of SA for a more in-depth investigation of the possibility of an SA interaction with PG regulation. SA-hyperaccumulating and SA-deficient lines were generated by expressing a salicylate synthase and a salicylate hydroxylase, respectively. SA was converted to SA-glycoside (SAG) and gentisic acid-glucoside (GAG) in the hyperaccumulating lines. SAG and GAG were very low in wild-type and were not detected in the SA-deficient lines. Despite these clear differences, no changes in PG levels were detected. These results suggest that SA is a potential precursor of PGs. Survival and establishment of rooted cuttings were negatively affected by SA-hyperaccumulation. Once established, however, growth rates were similar among plant lines, in sharp contrast to SA-over-producing Arabidopsis. SA-hyperaccumulating lines exhibited altered thermal tolerance, based on electrolyte leakage assays and metabolite profiling.
Together, our results provide support for a phenylpropanoid origin of PGs, and argue against the involvement of SA in PG biosynthesis. The data is consistent with complementary roles for SA and PG in Populus fitness. A number of other experiments were conducted to investigate the regulation of PG homeostasis in Populus. Administration of a putative PG precursor salicyl alcohol to cell cultures yielded the glucoside, salicin. Salicyl alcohol-feeding also altered the partitioning of carbon into condensed tannin (CT) biosynthesis, another quantitatively important phenylpropanoid product [6]. Salicyl alcohol-feeding induced expression of several glycosyltransferases (GT1), as well as genes associated with sucrose catabolism, glycosylation and the Krebs cycle, presumably to accommodate the increased glycosylation. Conversely, transcript levels of most of the flavonoid pathway genes were reduced, consistent with reduced CT synthesis. Given that glycosylation was the only PG biosynthetic step occurring in the fed-cells, the results suggest that glycosylation of phenolic products can play a role in regulating the tradeoff between competing chemical defenses, e.g., PGs and CTs.

Correlation analysis was used to identify PG-coregulated genes from a number of inductive treatments. One such candidate, SUT4 encoding a tonoplast sucrose transporter, was of particular interest because of the reported salicin transport activity of its Arabidopsis ortholog. RNAi-silencing of SUT4 altered sucrose distribution between source and sink organs, and reduced biomass by 20-30%, accompanied by altered biomass partitioning [7]. Chemical and molecular analyses revealed a complex network linking PG accrual and carbohydrate homeostasis. PG-coregulated GT1 members were also targeted for characterization, due to the prominent role of glycosylation in PG biosynthesis. We identified a novel salicyl alcohol glycosyltransferase (UGT71L1). Over-expression of UGT71L1 in transgenic Populus led to a ~2-fold increase in concentrations of salicin and salicortin in roots. The quantitative effect on secondary metabolism is significant, as PGs are the second most abundant non-structural phenolics, after CTs, in the roots of this poplar clone. UGT71L1 is phylogenetically distinct from the well-characterized SAGT11. It belongs to a Populus-specific clade with no close homologs in Arabidopsis, Vitis, Medicago and Oryza, consistent with the limited taxonomic range of PGs. Overall, the experiments described highlight the important contributions of sugar transport and phenolic glycosylation to PG homeostasis, while also showing that SA and PGs make independent but complementary contributions toward the maintenance of Populus fitness.

Plants size, shape and adaptability are determined in large by their capacity to sustain, spur, redirect or arrest localized and whole-plant growth. We show that GA signaling and metabolism determines the level and extent of shoot and root growth. Increase of GA concentrations or signaling leads to increased shoot growth but suppresses root development. These GA-related responses are underpinned by sets of highly specialized in their functions enzymes and signaling factors and cross-talk with other hormonal pathways. The differential effects of GA on root and shoot growth and development are likely associated with a regulatory mechanism responding to optimum and stress conditions. Ongoing work in the laboratory employs genomics and genetics approaches to more thoroughly understand poplar growth and development under stress conditions including nitrogen and water limitations. We use genetic networks analysis and forward genetics approaches to identify key regulators of poplar roots response to stress.

111 Regulation of shoot-system development in Populus

Shoot phenology interacts with crown morphology to determine leaf production and duration over the growing season and throughout a tree’s life span; and thus, this interaction has a major role in determining whole-tree photosynthesis and biomass yield. For several years, the pattern of shoot meristem activity determines Populus crown architecture, but after the first onset of flowering the specification of meristem identity (inflorescence vs. vegetative) also has a major influence on crown form. To study how shoot meristem activity and identity are regulated in Populus, we are focusing on two pathways that have been extensively characterized in annual plants: 1) the MORE AXILLARY BRANCHING (MAX) genes that are involved in the synthesis and perception of upward mobile strigolactones that inhibit axillary bud outgrowth, and 2) members of the TERMINAL FLOWER1 (TFL1)/FLOWERING LOCUS T (FT) and APETALA1/AP1/FRUITFUL/FUL gene families that regulate flowering. We are taking a multi-pronged approach that includes field and controlled-environment study of poplar transgenics, transcriptome analyses, cell-specific expression studies, and QTL and association mapping.

QTL mapping in a hybrid poplar pedigree localized three of seven poplar MAX genes in QTL for bud set and two MAX genes in sylleptic branching QTL. All MAX transgenes were established in a field trial and phenotyping of poplar transgenics, transcriptome analyses, cell-specific expression studies, and QTL and association mapping.

Recent work has revealed that poplar FT1 and FT2 have diverged in regulation and function with FT1 promoting the transition to flowering in response to winter temperatures, whereas warm temperatures and long days promote FT2 expression and shoot growth [1]. In Arabidopsis, FT activates AP1, a key regulator of flower initiation. Expression and transgenic studies in poplar indicate that similar to the two poplar FTs, poplar AP1 subfamily members have roles in both flowering and bud set in response to short-days and abiotic stress. Ongoing work is aimed at defining the roles of FT and AP1 modules in these processes and to
delineate the roles of the five different poplar AP1/FUL genes. Finally, TFL1 acts opposite to FT to promote vegetative meristem identity in Arabidopsis, and AP1 and TFL1 repress each other’s expression. The poplar TFL1 homologs, CEN1 and/or CEN2 have roles in maintaining vegetative identity and in the dormancy-growth transition [2] and we are currently working to define the individual roles of the poplar CENs and their relationships to FT and AP1 activities.

I12
The genomics of poplar-rust interactions to improve tree resistance against fungal disease
Louis-Philippe Hamel1, Barakat A, Carlson JE, dePamphilis C, Luthe DS, Yucer MC. With their long life cycle, trees must have accurate mechanisms to perceive microbial invasion and elaborate signalling networks in order to activate the appropriate defense response through transcriptional reprogramming. Transcriptional activators and repressors participate in the tight regulation of the stress response, which is key to minimize the fitness costs associated with an activated response. With the availability of its whole genome sequence, ease of growth and clonal propagation, and routine transformation, poplar (Populus spp.) is considered a model tree species for genomics research and also a good system in forest pathology [1]. Moreover, genomes of a corset of associated microorganisms are being sequenced including a tree pathogen, Melampsora poplar rust. We pursued various approaches to identify poplar genes involved in the interaction with the biotrophic Melampsora rust pathogen. Recent transcriptome analyses from our lab have shown that the expression of genes encoding several transcription factors are up-regulated during infection by Melampsora rust. Similarly we have also shown that mitogen activated protein kinases (MAPKs) are associated with poplar disease resistance against Melampsora rust [2]. New data obtained from various experimental approaches have directed our focus on two important families of transcription factors; the jasmonate ZIM-domain (JAZ) and Cys2/His2 zinc-finger protein (ZFP) families. We have identified a novel MAPK-interacting partner, PtiZFP1, which belongs to the C2H2 ZFP family of transcriptional EAR repressors. The JAZ family of transcriptional repressors were recently identified as key negative regulators of jasmonate (JA) responses. Transcript analyses show that some ZFP and JAZ members exhibit hormone-related expression profiles and up-regulation by rust infection. This up-regulation of JAZ and ZFP transcripts after rust infection strongly suggests that a hormonal response including JA is a key component of the poplar defence response against Melampsora. Late and sustained kinetics of PtiZFP1 and specific JAZ up-regulation suggest that the corresponding proteins may be required for late regulation of defense mechanisms. Several recent data have shown that proteolytic cleavage of transcriptional repressors is a general mechanism used by plants to activate gene induction. This mechanism is now well documented for jasmonate signaling, which depends on proteasome-mediated degradation of the JAZ repressors [3,4]. In the present work, we also obtain clear evidence that MAPKs promote degradation of PtiZFP1 through the 26S proteasome. Our work suggests that PtiZFP1 and JAZs are part of Melampsora specific defense responses, and by correlation as putative transcriptional repressors, participate in the regulation of the transcriptional responses downstream of these stress hormones. We hypothesize that the observed gene induction play a negative feedback loop needed to replace PtiZFP1 and JAZ proteins that were degraded following through the 26S proteasome. Newly synthesized repressor proteins could contribute to defense attenuation and therefore prevent a runaway response.

Figure 1(abstract I12) Proposed model of PtiZFP1 function in the plant defense response.
Based on our data, we propose a model (Figure 1) where two important families of transcription factors play a predominant role in poplar defense response to the biotrophic fungus *Melampsora*. The activation of poplar MAPKs would lead to PtiZFP1 degradation and as a result to transcriptional activation of defense-related genes. In parallel, we also observed that several genes involved in the JA response (including JAZ) are induced following *Melampsora* infection. This model highlights the importance of the 26S proteasome in regulating protein pools of transcriptional repressor. For future studies we intend to uncover which cis elements and target genes are recognized by PtiZFP1 and perform functional approaches to uncover JA-inducing proteins in plants.

During normal conditions, direct transcriptional repressors such as PtiZFP1 inhibit the expression of stress-related genes. Following stress perception, a MAPK signaling cascade is activated leading to phosphorylation of PtiZFP1. Phosphorylation targets PtiZFP1 for degradation via the 26S proteasome (26P), thus relieving repression of defense genes. Defense signaling in turn activates PtiZFP1 gene transcription in order to replenish normal PtiZFP1 protein levels and complete a regulatory cycle necessary to attenuate the defense response. A similar regulatory cycle exists for jasmonic acid (JA) signaling. JA biosynthesis is induced by stress which then promotes proteasome-mediated degradation of JAZ proteins. These indirect transcriptional repressors sequester the bHLH MYC2, thus inhibiting expression of defense genes under non-stressed conditions. Upon release, MYC2 ensures both positive and negative feedback loops by activating Lox3 and JAZ genes respectively. Confirmed and hypothetical pathways are presented in bold and dashed lines respectively.

There is an urgent need to determine the adaptive potential of forest trees given their importance in ecosystem functioning and the associated ecological and economic services they provide. Indeed, understanding rapid adaptation could lead to unnecessary recommendations such as the use of non-native (and perhaps non-adapted) genetic material for reforestation. Overestimating adaptive potential could have detrimental consequences if populations are not able to regenerate.

A critical step to study individual's and specie's responses to variation in climate is to examine the basis of adaptation (at the phenotypic and molecular levels) under natural conditions and across multiple years. In this context, these sessile and long lived species have emerged as a model system for studying adaptation into the wild. Whether forest trees will be able to adapt in situ fast enough to outstrip the rate of such modifications relative to their longevity is still largely debated and remains an open question.

The objectives of this presentation are three fold:
i/ provide an overview of the concept of ADAPTATION: a process whereby a genotype or a population becomes better suited to its habitat. Adaptation to climate change can occur through phenotypic plasticity (a mechanism involving genes which individuals can withstand large environmental fluctuation without genetic change) and evolution (i.e. response to natural selection pressure when the level of standing genetic diversity or diversity introduced by gene flow permits it).
ii/ provide some clues (from historical and contemporary data) on how closely can forest tree adaptation be expected to track climate change as rapid as envisioned for the future. They have high phenotypic plasticity which allows them to tolerate wide environmental variations during their lifetime. Besides, there are some evidence against the idea that rapid environmental changes overwhelms evolutionary processes preventing adaptation to local environments.
iii/ review related genes that matter for adaptation can be detected using ‘omics technology in combination with population and quantitative genetics approaches.

I6. WOOD FORMATION

I14 A systems biology approach to understanding the regulation of lignin biosynthesis
Vincent Chang
Forest Biotechnology Group, North Carolina State University, USA
E-mail: vincent.chang@ncsu.edu
BMC Proceedings 2011, 5(Suppl 7):14

Lignin is a complex phenolic structural component of the secondary cell walls of all vascular plants. It is an irreversible end point of a major metabolic pathway in plant secondary metabolism. Lignin is fundamental to the adaptation of plants to land, the evolution of vascular transport and the resistance of plants to pests and pathogens. Lignin is a major barrier to the utilization of biomass for energy, for papermaking, and for forage digestibility due to the interaction of lignin with cellulose in the plant cell secondary wall.

The past research on lignin biosynthesis is substantial, creating one of a few opportunities in higher plants to integrate genomics, proteomics, biochemistry, chemistry and modeling to develop a comprehensive understanding of biosynthesis and structure of a major component of morphology and adaptation. We are conducting a systems biology study on regulation of lignin biosynthesis in wood formation. We seek to build models to quantitatively illustrate how the entire pathway is organized and regulated and to reveal regulatory and metabolic flux control mechanisms, leading to lignin quantity and structures. We use the model woody plant, *Populus trichocarpa* (Nisqually-1), and the systems approach including advanced quantitative methods of genomics, proteomics, metabolomics, biochemistry and structural chemistry, to provide a comprehensive analysis of the regulation of lignin biosynthesis. A perturbation strategy is used to systematically knock down the expression of all pathway and regulatory genes known to be involved in lignin biosynthesis during wood formation, and the effects on lignin biosynthesis (gene transcripts, proteins, metabolites, quantity and structures) analyzed using advanced genomic methods available. This information forms the foundation of statistics-based mechanistic modeling and lignin quantity/structural predictions for a quantitative model of lignin biosynthesis. Details of systems data generation, data analyses and model development will be presented. Substantial data have been generated for gene-specific (amiRNA & RNAi) transgenic *P. trichocarpa*, enzyme kinetics, protein regulation and numerical modeling, and stable-isotope-dilution based absolute quantitation of proteins and of metabolites. These results will be discussed. Our long term goal is a predictive model of lignin biosynthesis and quantity/structure for greater understanding of the plant response to environmental stress and for more precise strategies to improve plant productivity and the production of energy, biomaterials and food.

I15 Ethylene signaling via Ethylene Response Factors (ERFs) modifies wood development in hybrid aspen

BMC Proceedings 2011, 5(Suppl 7):15

Background: The phytohormone ethylene (ET) has the potential to regulate secondary growth of plants and wood formation in trees.
Application of exogenous ethylene or its in planta precursor, 1-aminoacyclopropane-1-carboxylic acid (ACC), to wood forming tissues of hybrid aspen (Populus tremula x Populus tremuloides) enhances xylem growth [1]. In the same study it was demonstrated that stimulation of enhanced xylem formation (tension wood, TW) at the upper side of leaning stems is mediated by endogenous ET. The production of endogenous ET in TW forming tissues is further supported by the increase of ACC oxidase gene transcript and enzyme activity on the TW side [2].

The ET perception and signal transmission cascade in Arabidopsis has been linked to the transcriptional activation of Ethylene Responsive Factors (ERFs) [3,4]. As transcription factors, ERFs regulate the expression of various specific downstream target genes by binding to cis-elements in their promoters [5]. We hypothesize that ERFs participate in xylem development through ethylene signaling and that they are involved in ET responses during TW formation.

Results and conclusions: We identified 169 ERF genes in the Populus trichocarpa genome versions 2.0 and 2.2 using regular expression method and pfam search for the ERF domain. These ERFs grouped into 11 distinct groups, similar to ERFs identified in Arabidopsis and rice [6]. Using qPCR we showed that a majority of the ERF transcripts were detectable in stem tissues of in vitro or greenhouse grown hybrid aspen. The remaining set of all ERFs to short term ACC treatments (10 days in vitro plants) and to short or long term ethylene treatments (24 or 2 weeks, greenhouse grown plants), was assessed by qPCR. Most of the ERFs responded to at least one of the treatments, mostly by increased transcript accumulation. We identified ERFs that were specifically induced within the early ACC/ET- or the late ET-response. In addition, some ERFs showed prolonged induction up to 2 weeks of ET treatment. These different transcript patterns indicate that different ERFs may be involved in distinct, temporally distinguished processes during the ACC/ET-induced secondary xylem growth response.

According to their expression and capacity to be induced by ET or ACC, we selected 26 ERF candidates and investigated whether those were responsive to endogenous ET-signals in leaned stems during TW formation. We compared the induction of those 26 candidate ERFs in TW with ERF accumulation during long-term (2 weeks) ET treatment. Interestingly, a significant overlap of ERF induction in both conditions was found. From the 20 ERFs that were induced after long-term ET treatment, 16 had an increased transcript abundance during tension wood formation. This indicates that on an ET transcript basis, tension wood formation is largely comparable to a long-term ET treatment.

Based on the transcript data, twenty ERFs were selected for overexpression in hybrid aspen cambium/xylem under the pLMXS promoter [1]. Successful overexpression of the selected ERFs in transgenic plants was confirmed and two to seven lines of each overexpressed ERF were phenotyped in a greenhouse trial. In general, ERF overexpression caused only mild alterations of overall plant stature (height and radial growth). Only overexpression of one ERF candidate led to a severe dwarf phenotype with thin stems, reduced fiber and vessel size, reduced height growth and smaller leaves. The absence of any striking phenotypes in all other plants suggests that other regulators in addition to the overexpressed ERFs may be necessary to mimic the enhanced growth response observed during ET/ACC/TW mediated stimulation of secondary xylem growth.

A Fourier-Transformed Infrared spectroscopic and Pyrolysis GC-MS based screening of five lines for each of the 20 overexpressed ERFs revealed that five ERFs led to changes in cell wall composition in xylem tissues when overexpressed. This suggests that these ERFs have the ability to modify cell wall composition in forming wood tissues and may regulate the expression of cell-wall biosynthesis genes. This hypothesis is now under further investigation.

I16 How sweet it is – making the most of carbohydrate metabolism
Shawn Mansfield
Department of Wood Science, University of British Columbia, Vancouver, Canada
E-mail: shawn.mansfield@ubc.ca
BMC Proceedings 2011, 5(Suppl 7):16

Like all plants, trees constantly monitor endogenous and environmental cues, and use this information to make adjustments in resource allocation, both to maximize resource acquisition and to minimize exposure to deleterious phenomena. To accomplish this, trees possess mechanisms that integrate and interpret the information provided by internal and environmental signals. Ultimately, these phenomena are controlled at the level of gene expression, which consequently translates into the accumulation of a variety of soluble metabolites, including carbohydrates. Trees are relatively “plastic” in their ability to allocate resources, and such plasticity has an adaptive significance in that it allows trees to (i) match resource allocation with resource acquisition, (ii) acquire new resources more effectively, and in some instances (iii) avoid adverse conditions. The inherent plasticity in resource acquisition can have a profound effect not only on the development and physiology of trees, but also on the industrial harvesting and utilization of the terminal lignocellulosic resource. Photosynthetic carbon capture by trees represents a major sink for atmospheric CO₂, ultimately terminating in the synthesis of a secondary plant cell wall – a complex matrix of polysaccharides intricately linked to lignin. Therefore, engineering plant where resource allocation is directed to vegetative biomass and fibre properties should have an effect on the plant cell wall traits. As such we have targeted the biosynthetic processes governing sucrose metabolism by mis-regulation of key enzymes associated with the catabolism and anabolism of sucrose in attempts cellulose production – both quantity and quality. This paper will discuss the results of these efforts, and illustrate the altered performance of such plants for industrial use.

S7. PROPAGATION AND IN VITRO TECHNOLOGIES

I17 From genes towards products and the significance of gene delivery
Magnus Hertzberg
SweTree Technologies AB
E-mail: Magnus.Hertzberg@SweTree.com
BMC Proceedings 2011, 5(Suppl 7):17

SweTree Technologies is a plant and forest biotechnology company providing products and technologies to improve the productivity and performance properties of plants, wood and fiber for forestry and fiber related industries. In the area of Biotech Trees, we have been testing and developing genes and biotech trees. Since 2002 we have successfully screened well over one thousand genes in our gene testing program. The program has been mainly directed towards increased growth, improved wood properties and stress tolerance. The current outcome of this program will be presented. The primary gene developing program is performed in hybrid aspen for which we have a very efficient transformation protocol.
However for practical tree biotechnology the genes and DNA constructs have to be transformed into the best commercial clones. Therefore we have been setting up efficient transformation protocols for both Eucalyptus and Populus elite clones. Another crucial part of a practical tree biotechnology program is to test the GM trees with commercially interesting genes under field conditions. We have initiated field trials and plan to have over 35 different types of transgenic trees in field trials by the end of this year. These field experiments are performed by SweTree or in collaboration with academic partners. The importance and requirements for elite clone transformation and field trials will be discussed in the presentation.

I18
Hybrids and mini-cutting: a powerful combination that has revolutionized the Eucalyptus clonal forestry
Teotônio Francisco Assis
ASSISTECH LTDA
E-mail: assiste@terra.com.br
BMC Proceedings 2011, 5(Suppl 7):s18

Background: Eucalypt canker disease (Chrysoporthe cubensis) was the major obstacle of the concept of eucalypt clonal forestry in Brazil. Initially clonal forestry was based on outstanding spontaneous hybrids resistant to canker disease. Since the recognition that cloning superior inter-specific hybrids could be an important general strategy, several crosses were made for many different purposes, especially pulp & paper, charcoal and more recently veneer and solid wood. This strategy has been responsible for a significant advance in the forest productivity of Eucalyptus. The underlying foundation for this strategy has been the exploitation of heterosis observed in most inter-specific crosses.

Due to its importance, hybridization and cloning currently constitute a key component of almost all forest-based industrial plantations in Brazil. Significant progress has taken place in the last few years with the different techniques used to carry out controlled crosses and cloning.

Controlled crosses: The fact that Eucalyptus flowers are hermaphrodite and protandrous makes the traditional method of controlled crosses difficult to perform. This method is based on the exploitation of protandry, which involves emasculation and isolation, prior to pollination. It needs several visits resulting in a technique of low operational yield.

After discovering that different treatments in stile and stigma during anthesis could immediately induce flower receptivity [3], it was developed the OSP (One Stop Pollination) technique [4]. Later it was found that this receptiveness could be achieved just before anthesis [5]. Combining these two discoveries a new technique was developed [2], called Artificially Induced Protogyny (AIP). This technique consists of the artificial "transformation" of protandry into protogyny, obtained by cutting the top of the floral bud operculum together with the upper third of the stile. This is done during the pre-anthesis stage, i.e., when the flower is still closed. Pollen can be applied immediately after induction. Additionally the concept of indoor breeding orchards was developed, preculturing the seed to isolate individual flowers, umbels or branches, enabling the isolation of whole plants in a collective way.

The combined use of these technologies (AIP and indoor breeding orchards) currently allows large scale controlled crosses, and enables the production of highly superior full-sib families, a task formerly considered technically and economically difficult in Eucalyptus. Operational productivity improved from 35 to 400 pollinated flowers/person/hour.

Cloning techniques: Cloning techniques have been significantly enhanced in the last years. The first major leap occurred in 1992, when micro-cutting was invented [1] and later mini-cutting. The micro-cutting is a rooting method, where the propagules are obtained exclusively from shoot apices, originated from micro-propagated plants. Mini-cuttings, on the other hand, come from axillary sprouts of rooted stem-cuttings. After the establishment of the mini-clonal hedges, the two techniques are identical, varying only in the origin of the initial source of propagules. Micro-cutting and mini-cutting are the most modern concepts for large scale cloning of Eucalyptus species. They are implemented using hydroponic systems such as sand bed with drip irrigation or intermittent flooding with very specific nutritional parameters that allow commercial scale production of sprouts. Although significant progress has been made in these robust and functional systems, new approaches to clone Eucalyptus species are opening important opportunities to improve operational results and also contemplating recalcitrant species in the general hybridization & cloning strategy. One of these new approaches is cloning selected trees from lignotuber tissue. Tested originally at Arcelor Mittal Bioflorestas, cloning from lignotubers constitute a new advance to be soon incorporated in the operational procedures. Another promising approach is to cover mini-stumps with mini-tunnels. Preliminary results of this method at Aperan Bioenergia have shown that productivity, rooting rate and root quality are improved, reducing the formation of callus.

After more than thirty years of experience on deriving clones from inter-specific hybrids, this general strategy, together with the evolution of silvicultural practices, have been the major drivers of the progress experienced in forest productivity in Brazil. The evolution of pulp productivity obtained by cloning superior hybrids has been impressive. While in 1970 the average MAI-Cellulose was 6 ton/ha/year it now reaches 12 ton/ha/year. New projections now work with the possibility of achieving a potential productivity of about 16 ton/ha/year by 2015. One of the key elements for this further jump in productivity is the rapidly increasing use E. globulus in hybrid breeding programs. E. globulus has superior wood qualities such as low lignin content and high S/G ratio (one of the highest in woody plants) that result in easier cooking, low specific consumption (high wood density and pulp yield) and good bleaching ability. The use of adapted species and clones in crosses with E. globulus is yielding a new breed of elite hybrid clones for subtropical and tropical areas.

BMC Proceedings 2011, 5(Suppl 7):s19

Eucalyptus is the second most planted tree on earth. Despite this ranking, its mature breeding programs, clonal propagation and deployment and short rotation time make it a leading target for biotechnology improvement. The recently completed eucalyptus genome project provides an enormous opportunity for understanding and developing new traits for eucalyptus forestry. The main obstacle for widespread trait enhancement remains the recombination of commercial eucalyptus clones to transformation and thus the lack of a suitable prototytping system for this species. We believe that the future success of trait development in eucalyptus will be enhanced by close collaboration between academic centers and industrial partners. Some of FuturaGene's models for academic collaboration will be described in this presentation.

An example of such potential collaborations may involve BRASUZ1, which constituted the germplasm base for the eucalyptus genome project. This key clone was donated by Suzano Pulp and Paper, FuturaGene's parent, to the genome project. We will present our progress with the transformation protocol for BRASUZ1, which could provide a platform for collaborations. We will also present our perspective on the development of improved transgenic eucalyptus, and an outline for such development programs.

**BMC Proceedings 2011, 5(Suppl 7):230**

Background: The International Year of Forests - 2011 [http://www.un.org/en/events/iyof2011] will be a milestone for forest tree genomics. The draft genome sequence of Eucalyptus grandis was released in January 2011 in the USA (Phytozone [http://www.phytozone.net]) and in Belgium (BOGAS, [http://bioinformatics.psb.ugent.be/webtools/bogas/]). The genome sequencing was funded by the US Department of Energy (DOE) and performed at the DOE Joint Genome Institute (JGI) in collaboration with members of the Eucalyptus Genome Network (EUCAGEN, [http://www.eucagen.org]) who contributed genetic materials, linkage maps, EST resources and bioinformatics support. The E. grandis genome together with that of Populus trichocarpa (1) and other woody plant genomes recently completed (e.g. Vitis, Cacao, Prunus, Citrus and Malus) will provide excellent opportunities for comparative studies of the unique biology of woody plants. Eucalypts are currently the most widely grown hardwood fibre crop in the world and eucalypt breeding programs will benefit greatly from the new genomic resources. The reference genome sequence of Eucalyptus, a foundation tree genus in Australia comprising more than 70% of the native forest estate, will also offer important benefits for ecological and evolutionary biology studies. We report the sequencing, assembly and annotation of the E. grandis genome.

**Genome sequencing and assembly**: Whole-genome (8X) shotgun sequencing was performed for a partially inbred (S1), 17-year-old tree of E. grandis (est. genome size 640 Mbp, n = 11) at BRASU1 (Suzano, Brazil). A total of 7.7 million Sanger reads (5.4 Gbp) were produced from plasmid, fosmid and BAC libraries. An inbred genotype was selected to circumvent and evolutionary biology studies. We report the sequencing, assembly and annotation of the E. grandis genome.

Genome-wide association studies (GWAS) have been used to identify regions of the genome related to various phenotypes in humans, corn, rice and cattle. Successful application of this approach to bioenergy crops such as Populus requires 1) an appropriate mapping population, 2) high-quality...
With the efforts of the Joint Genome Institute (JGI) through the EUCAGEN Euca
culus Genome Network reaching the final release of a Eucalyptus gran
ids reference genome (BRASUZ21), it is anticipated that this accomplishment
will profoundly shape the future research of this global tree genus [1]. One of
the first steps toward this end has been the refinement of the genome
annotation. Robust models have been generated for protein-coding genes.
Here we report the annotation of other pivotal genome constituents,
transposable elements (TE) and micro RNA genes. TEs are not only the
most dominant elements but are also major drivers of genome plasticity.
Several bioinformatic strategies were employed to perform “de novo” and homology
based prediction of repetitive elements [2]in the current genome release
(version 1.0). A total of S3 distinct TE families could be identified, with the
retrotransposon super-family being widely over-represented, as observed for
the majority of plant genomes sequenced.
Micro RNAs (miRNA), key players in post-transcriptional gene regulation,
were annotated using a combination of massively parallel sequencing of small
RNA libraries and a genome-wide computational screening to
ascertain a compatible secondary structure of the precursor. Both experimental
and “in silico” evidences enabled the annotation of 206
distinct miRNA loci comprising 36 different mir gene families including
several miRNA isoforms. The blueprint provided by a high-quality reference
genome, both in terms of sequence completeness and annotation, will
leverage efforts to better characterize intra- and inter-specific sequence
variation underlying the marked phenotypic differences among
the hundreds of species comprising this genus.
Recent advances of DNA sequencing technologies permit a comprehensive
interrogation of several other individuals at a fraction of the cost. In this
context, we have used illumina (2x75bp) short read sequencing data of
E. globulus clone X46 generated by JGI and made available through the
EUCAGEN network to carry out two comparative genomics experiments.
From 40X raw sequence data provided it was possible to use an equivalent
of 20X coverage (~12Gbp). We first attempted to perform a “de novo”
assembly using VELVET [3]. A total of 161,000 contigs were obtained the
largest one sizing at ~3,5kb. In spite of the easy access and low cost of
next generation sequencing technologies, these results suggest that even
for relatively small forest tree genomes, current technical and
computational limitations preclude comprehensive assembly, likely due to
the ubiquitous occurrence of repetitive elements in such genomes.
Nevertheless when we mapped the E. globulus sequencing data against
the BRASUZ1 reference genome, 55% of the reads could be mapped with
high confidence. From these, approximately 800,000 high quality single
nucleotide polymorphisms (SNPs) could be identified clearly showing the key
role that the reference genome will have for future genomic undertakings.
The sheer number of molecular markers discovered in this
experiment not only fosters more powerful studies on the evolutionary
history and 100 native genotypes of eucalypts, but also inaugurates a new
era in molecular breeding of species of this genus, providing genome-wide
coverage for genomic selection and association studies.

BMC Proceedings 2011, 5(Suppl 7):I23

Background: Global warming, environmental disasters, and increasing oil
costs have catalyzed a worldwide trend to use plant biomass as a
renewable source for liquid biofuels and bio-based materials. Plant biomass
can be processed into fermentable sugars by enzymatic depolymerization of
the cell wall polysaccharides, followed by fermentation. However, the
presence of lignin in the cell wall constitutes a major recalcitrance factor
because it limits the accessibility of polysaccharides to the cellulose
microfibrils. To overcome this hurdle, plant biomass is pretreated in a costly
and energy-consuming process. One approach to overcome the recalcitrance
problem is to engineer lignin amount or alter its composition, to make lignin
more susceptible to chemical degradation [1]. Cinnamoyl-CoA reductase
(CCR), the enzyme that converts feruloyl-CoA into coniferaldehyde, is
considered the first enzyme in the monolignol-specific branch of the
phenylpropanoid pathway. Poplar trees down-regulated in CCR have been
produced in the early nineties and planted in a field trial in France to
produce sufficient wood for small scale chemical pulping tests [2]. These
trees had 20% lower lignin levels and relatively more cellulose per gram of
wood [2]. Given that lignin is one of the main limiting factors limiting the
conversion of plant biomass into fermentable sugars, and that poplar is
considered as a promising second generation biofuel crop, we have re-
grown these trees in the greenhouse and in the field, and evaluated wood
produced from these trees by saccharification experiments.

Methods: Cinnamoyl-CoA reductase (CCR) expression was down-regulated
in poplar by sense and antisense strategies [2]. Transgenic trees were
evaluated for lignin amount and composition [2] and for sugar release by
saccharification assays [3]. After obtaining permission from the regulatory
authorities, two transgenic lines were planted in a field trial in Belgium and
in two in a field trial in France, both under short rotation coppice culture to
maximize biomass production. Wood was saccharified with and without
acid pretreatment.

Results: Wood from CCR down-regulated trees that were grown in the
greenhouse was saccharified with and without acid pretreatment.
Interestingly, wood from the transgenic lines released more glucose in
saccharification assays performed without pretreatment than wood from
wild type trees when saccharified with a pretreatment, demonstrating the improved processing of the cell wall polysaccharides by the enzyme cocktail. These promising results prompted us to ask permission for a field trial to verify whether wood from these trees, when grown in an open field, would still be more easily saccharified. After all, when trees are grown in the greenhouse, they do not experience wind, rain and seasons, and they need to be stacked to grow upward. After a one year long calvary to obtain regulatory permission for the Belgian field trial [4], the trees were grown under short rotation coppice culture in replicated clonal blocks in a small plot of a total of ~ 500 trees. The plot has a fence and is surveilled by cameras. In Spring, the trees are regularly monitored for flowering as they are not allowed to flower. Flowering is not expected because the coppice cycles are as short as 3 years. The possible effects of the low lignin trait on rust infection and insects is being monitored, but it is not expected that these effects will be larger than those associated with conventionally bred poplar hybrids or will be specific to the transgenic trees taking the large genetic diversity of the wild poplar germplasm into account. Activist groups that are concerned that these trees pose different risks than conventionally bred hybrids or pose a risk for human health are invited for a discussion with scientists and the biosafety manager at VIB.

After one year of growth in the field, trees were coppiced to allow the development of fast multiple shoots in the next spring. The basal 20 cm part of the stem was debarked. Wood harvested from wild type trees was white in appearance, but wood from the transgenic trees was red-brown, most likely due to reactions with ferulic acid, derived from the substrate of CCR, in the cell wall [5]. Importantly, the red coloration was not uniform, but varied significantly in a single trunk, and among trunks from clonally propagated trees. Saccharification potential increased to ~50% per gram dry weight. Our data show that reducing lignin amount in trees improves saccharification potential and should reduce the chemical or energy cost of biomass pretreatments. The trees will be harvested again in winter 2012-2013, i.e. three years after the first coppice. This should provide sufficient biomass for evaluation at semi-industrial scale at the pilot biorefinery in the Port of Gent [6].

BMC Proceedings 2011, 5(Suppl 7):24

Background: Eucalyptus species are among the fastest growing woody plants in the world and represent about 8% of all planted forests (~18 million hectares) grown in 90 countries [1]. Only a limited number of species are grown commercially, and these have been the focus of extensive breeding to improve desirable wood properties such as basic density, cellulose content, fiber length and improved growth. Improved Eucalyptus varieties grown in managed plantations as a source of timber and pulpwood have provided socio-economic benefits for both small and large land owners. Eucalyptus also provides a cost-effective source of lignocellulosics for the production of energy and advanced biofuels. However, the large scale plantings of the most productive Eucalyptus species in the Southeast U.S. are currently limited to regions of central and southern Florida where no hard freezes occur in winter. Plantings of hardwood species to support the traditional forest industry in the Southeastern U.S. are infrequent due to slow growth rates and high plantation establishment and management costs. The biotech Freeze Tolerant Eucalyptus would provide an economically viable plantation hardwood for the Southeastern U.S.

Methods: Genetically engineered Freeze Tolerant Eucalyptus (AGEH427) was developed by the introduction of plasmid pA8CTEO1 into the EHI genotype of E. grandis x E. urophylla. AGEH427 was developed by the introduction of plasmid pA8CTEO1 into the EHI genotype of E. grandis x E. urophylla using the Agrobacterium transformation system described by Cheah (2001) [2]; pA8CTEO1 contains a CBF2 expression cassette comprised of Arabidopsis cold-inducible promoter n29A [3] driving the Arabidopsis CBF2 (Cold Responsive Factor) CONA [4,5]. It also contains a pollen control cassette consisting of a modified barnase gene from Bacillus amyloliquefaciens under the control of a Pinus radiata anther-specific promoter (PrMC2) [6]. Single insert, backbone free transgenic lines were vegetatively propagated to enable 21 replicated field trials established at eight different locations representing USDA Hardiness Zones 8a (potential kill zone), 8b (target freeze-stress zone), and 9a (freeze stress-free zone) across the Southeast U.S. A simple comparison of pre-winter and post-winter live height measurements was used to calculate a percent dieback of the main stem, and provided appropriate assessment of freeze tolerance and growth performance under field conditions. Data were collected over five winter/growing seasons. Pollen ablation was studied by collecting multiple flowers from field grown transgenic and non-transgenic trees prior to anthesis and microscopic assessment of the frequency of normal pollen.

Results: The transgenic line AGEH427, had significant freeze hardiness that enabled it to grow in USDA Hardiness Zone 8b. The growth of AGEH427 was comparable to EHI non-transgenic control trees when grown under low- or no-freeze challenge conditions (Zone 9a). In the target freeze-challenged environment (Zone 8b), AGEH427 grew better than the non-transgenic control. After the severe winter of 2009/2010 at a site with a minimum temperature of 16.8 °F, the average live height of control trees was approximately 0.3 feet as compared to 52.4 feet for AGEH427. AGEH427 had approximately 10% dieback from the top. In the zone 8a (winter temperatures as low as 14.4°F), complete dieback and defoliation were observed, with post-winter tree heights for both AGEH427 and the non-transgenic control being only 0.1 ft. AGEH427 also did not produce pollen, whether or not it was grown in freeze challenged locations. No pollen was produced over multiple years, different flowering seasons, different sites, and different physiological ages of trees while the control trees did produce pollen. Additional phenotypic evaluations of AGEH427 in comparison to the control were performed in field studies across a broad range of environmental conditions in the Southeast U.S., and no differences, other than the freeze tolerance and pollen ablation traits were observed. Neither the transgenic nor the control trees demonstrated any tendency to spread beyond a managed plantation, with low seed set and lack of any seedling volunteers observed in the field trials.

Conclusions: The cumulative multi-season data obtained from these trials demonstrated conclusively that the freeze tolerant trait in AGEH427 enabled this tropical tree to grow in the subtropical, freeze-prone USDA Hardiness Zone 8b. The productivity of AGEH427 makes it ideal as a short-rotation plantation hardwood in the Southeast U.S. The yield achievable with freeze tolerant Eucalyptus is predicted to meet the required productivity for an economically feasible hardwood plantation to meet traditional forest industry and bioenergy needs [7]. There is no evidence from the literature or from our field trials which indicates that EHI-427 would be invasive or negatively impact endangered species. EHI-427 is currently the subject of a petition for deregulation in the U.S.
In the 1980s, when the production of transgenic plants was first demonstrated and was soon followed by production of healthy transgenic poplars in the US and then in Belgium, many of us, including some of the most conservation minded in forestry science, embraced genetic engineering/genetic modification as an important new technology for forestry. We had this sense of following the yellow brick road to Oz. It seemed that we could finally get beyond the narrow limitations of the slow outbreeding, quantitative breeding system, and begin an era of qualitative genetics to complement the dominant quantitative genetic paradigm. Unfortunately, when we got closer to the Wizard of Oz things looked a bit different than on the famed Yellow Brick Road (Figure 1).

What happened? Most important, the technology, and how it was structured, ran into a social and political buzz-saw. The world was becoming richer and more sensitive, both in terms of environment and respect for life. A diversity of social movements were taking place, powered by the new internet, that was uncomfortable with the notion of transgenics and who controlled them, and a number of organizations with resources and power opposed transgenics at every turn. A patent system was put in place that only very large companies or a few wealthy foundations could afford to negotiate. Rich consumers and vulnerable consumers sensed risk and little or no direct benefit to them, and thus also opposed the technology in large numbers. Regulations were pushed through that made the costs of field research, marketing, permits, international trade, liability insurance, and labeling huge barriers to investment and commercial adoption. Nearly the only crops to survive produced huge economic benefits and had to be pushed through the regulatory system by the multinational companies that consumers feel the least trust in.

Unfortunately, national and international regulations, once in place, are very hard to change—so this legacy will be with us for many years. Moreover, because the regulations treat all transgenes as hazards until

Figure 1(abstract I25) On the road to transgenic Oz in the early days of plant and forest biotechnology.
“proven safe,” they pose severe problems for conducting high quality field trials of most types of transgenic forest trees. This is a result of their wild and feral relatives, low level of domestication, and ability to produce pollen and seed that can move over large distances. Thus, it’s very hard to integrate transgenic trees into conventional breeding and field testing programs—which is essential for their development and application. Meanwhile, social perspectives and the structure of research funding has led to extraordinary scrutiny and amplification of every possible risk of transgenic trees, usually far out of proportion to its significance compared to conventional agriculture and forestry breeding. Thus, the trip has felt much more like a certain Electric Kool-Aid Test (Figure 2), than a normal technological progression, and not at all like the start of the trip to Oz. On the science side, despite our early successes, when we finally got to meet the Wizard, there was also a number of revelations that gave us pause about the robustness of transgenic tree biotechnology, and most remain significant to this day. 1) It was much harder to transform/
regenerate most commercially important forest tree species/genotypes than we had imagined, and very little in the way of public research funding has been directed to overcome this in a meaningful way. 2) There was a great deal of hype about some of the early successes, such as in the area of growth rate improvement and lignin modification, with insufficient field trials to judge their true merit. Many have not proven themselves, but the results are often hidden by business confidentiality, academic self-interest, and a paucity of high quality field research. 3) Beyond 5SS-type overexpression for traits like herbicide and Bt-insect resistance, the tools in place for control of gene expression were found to be coarse, unpredictable, and imprecise, likely due to lack of control insertion location, chromatin state, and poor understanding of RNAi/siRNA mechanisms. 4) While genetic containment would solve a lot of social and regulatory problems, due to high social concerns, short term funding, strict regulations over field trials, and immature technology, it’s unclear if we can attain, in the near to middle term, the nearly perfect level of predictable, field-validated containment that appears to be required. 5) The extraordinary advances in genomics and phenomics in conventional breeding, combined with the high costs of regulations, are pushing transgenic applications to focus on the most new, novel, and valuable applications that cannot be attained by conventional or genome-assisted breeding—which are also those for which attaining regulatory approval will be most difficult. 6) Meaningful, field-based ecological studies of fitness and non-target effects, especially of pest-resistant, stress-resistant, bioindustrial, and bioremediation types of transgenic trees, have not been conducted—leaving a wide swath for models and speculations of severe ecological impact that are likely to be vastly overstated—but push regulations toward ever greater stringency. In sum, a great deal of fundamental science, from the genetic to the ecological, and technology development to efficiently identify and transfer genes and pathways, remains to be done by the next generation of scientists and practitioners. Propelled by the ongoing successes of some pioneering companies, I sense that transgenic forest biotechnology, though facing great difficult challenges at present, will “keep on trucking” in the parlance of “The Trip” (Figure 2). This will be driven by science and technology successes that continue at an impressive rate; urgency in finding solutions in the face of severe global economic and environmental problems; and the human thirst for novelty, innovation, and truth.

KEYNOTE LECTURE PRESENTATION

K1 Exponential advances in Forest Genetics: the past 25 years and the next 25 weeks
Ronald Sederoff
Forest Biotechnology Group, North Carolina State University, USA
E-mail: ron_sederoff@ncsu.edu
BMC Proceedings 2011, 5(Suppl 7):K1

A history of Forest Biotechnology will be briefly reviewed, from the first cloned tree gene, transgenic trees, DNA markers, genetic maps, QTLs, mapping to genome sequencing. Perspectives of newer methods and their applications will be discussed, including integration of genomics and RNA-seq, metabolomics, and proteomics. New applications may be anticipated or expected for breeding, vegetative propagation, phenotypic plasticity, epigenetics, symbiosis, adaptation to biotic and abiotic stress and the directed evolution of some forest tree species. Forest Biotechnology began over 25 years ago with the advent of new technology of molecular genetics able to advance the fundamental and applied science of forest trees. Methods of gene cloning and gene transfer hold the promise of bypassing the long generation times that made genetic analysis and breeding so difficult. This vision has come to pass and the presentations of this meeting show how far we have come. Today, we are deeply involved in the next generation of genetic technology, a second revolution, using genomic sciences, based on the technology and concepts derived from whole genome sequencing, with the same objective, advancing the fundamental and applied science of forest trees.

The path ahead appears to have a third phase, based on an extension of the genomic paradigm, to systems biology and predictive modeling, directed to the same basic goals. Each new phase has been highly integrative, the first bringing molecular genetics into many traditional disciplines. The second phase, integrated areas of molecular and quantitative genetics with high throughput processing and bioinformatics. What appears to be the third phase will extend this paradigm to incorporate the chemistries of proteomics, the chemistry of metabolomics, and the organization, structure and dynamics of cell biology and whole plant physiology. This integrated paradigm further incorporates an engineering perspective and describes the integrated data as predictive mathematical models, subject to experimental test and manipulation. Much of this new biology will be at the interface of biology and systems engineering. Biologists will learn to think like engineers, and engineers will learn a lot of biology. In time, the distinctions between these disciplines may be lost.

What makes a tree a tree? We now know that a relatively small number of genes regulate the woody phenotype, because a small combination of gene mutations can produce a woody form of Arabidopsis. Similarly, small numbers of genes regulate key aspects of tree dormancy. Much remains to be determined regarding the control of tree growth and development, and little is known about the genetic basis of the wide diversity in morphology, metabolism and adaptation. Beyond the descriptive understanding of tree phenotypes and their diversity, lies the evolutionary question, how did the diversity of trees get to be that way?

Comparative genomics has been a powerful tool to derive gene function by comparisons of woody and herbaceous plants, because a large number of functions are conserved. A major barrier to a broad understanding of trees and all other plants still lies in the lack of information on the function of the majority of plant genes. The functions of most genes are known only by superficial annotation based on the time and place of transcript expression, or response to an external stress. Even for many genes of presumed known function, we do not know if that is the only function or the primary function. Even as more genes are subjected to gain of function /loss of function tests, interpretation suffers from effects of redundancy and lethality.

In the near future, genomic scale integration of processes at the levels of molecules, cells, tissues and organisms, as part of a systems biology approach, will bring about progress toward this goal. This goal appears daunting. One challenge comes from the knowledge of epistasis, or genetic interactions, that indicate substantial complexity even for simple traits. QTL analysis provides a general picture of this complexity, with a frequent genetic architecture of a small number of genes of large effects with a larger number of genes with small effects. Thanks to genomics and computers, the quantitative effects of a large number of genes may now be studied at the molecular level as is being done for genomic selection.

Traditionally, new concepts and technology developed in model systems see earlier applications in medicine and agriculture than in forestry. The lag time may be decreasing. The paradigm for genomics was established by the human genome project, where the draft sequence was initiated in 1989 and a first draft released in 2000. The sequence of Arabidopsis was completed in 2000, rice in 2002, and the first tree genome, black cottonwood, completed in 2006. We see application of new technology to traditional problems, in some cases with great success, and in others with great promise.

Only a few years after gene transfer was demonstrated in model plants, an herbicide resistance gene was inserted into poplar and a tree regenerated. Deployment of genetically modified crops has met with resistance, however, today worldwide; there are about 120 million hectares of GM crops, with half in the USA. GM trees are still highly regulated in the US. In China, GM trees have been widely deployed in the last decade. GM trees still face substantial resistance in the US and more so in Europe. Chestnut serves as an important model for a Genetically Modified Tree. The prospects of development of a blight resistant American chestnut appear quite good based on a combination of backcross breeding; map based cloning and genetic transformation. A genome sequence for Chinese chestnut is in progress (Carlson et al.). The use of gene transfer to promote restoration is compelling because of the high value of the species, and because GM may be required to restore the species. The restoration of the American chestnut would have great value to Appalachian forest ecosystems, as a resource of high value wood, and potentially for bioenergy. The restoration would serve as an example for the application of biotechnology and genomics to many valuable species currently threatened by pests and pathogens or climate change.

**01 Comparative genomics of resistance of spruce to the white pine weevil in British Columbia**
Kermit Ritland1, Sébastien Verne1, Barry Jaquish2, Carol Ritland1
1 University of British Columbia, USA; 2 Ministry of Forests, Lands and Natural Resource Operations, USA
E-mail: kermit.ritland@ubc.ca

BMC Proceedings 2011, 5(Suppl 7):O1

We present results of two large scale comparative studies of the genomic basis of resistance of interior spruce to the white pine weevil. Both volume growth, the main objective of the spruce breeding program in British Columbia, and white pine weevil resistance, are examined. "Interior spruce" is a species complex involving mainly Picea glauca (White spruce) but introgressed with P. engelmannii (Englemann spruce), depending upon locality. In the first study, we compared constitutive expression of 17825 genes between 20 resistant and 20 susceptible trees to the weevil; 54 upregulated and 137 downregulated genes were found in resistant phenotypes, with implications discussed in regard to volume growth. In particular, we will be surveying these genes for SNPs that differ between these two classes of trees in the next year. In the second study, we developed a 1536 Illumina SNP chip based upon candidate genes for weevil resistance. In a novel experimental design, we assayed 945 open-pollinated progeny of the Prince George breeding population (176 parents); and 654 open-pollinated progeny of the Prince Rupert breeding population (134 parents); parents were also genotyped. Within each family of 100 progeny, we identified the highest ranked 3 progeny and the lowest ranked 3 progeny, based upon BC Ministry of Forests scores for volume growth and resistance. These were genotyped and used in a novel test analogous to the transmission disequilibrium test to detect both SNP associations and QTLs linked to SNP markers. Discoveries about associations and QTL are discussed, with the added caution about genotyping error. Both studies illustrate how operational tree breeding populations can provide valuable inferences about tree genomics.

**02 Genomics of adaptation and wood properties in Populus trichocarpa**
Carl Douglas
University of British Columbia, USA
E-mail: carl.douglas@ubc.ca

BMC Proceedings 2011, 5(Suppl 7):O2

Populus trichocarpa [black cottonwood] and P. balsamifera [balsam poplar] are native to North America where large natural populations exist. P. trichocarpa has an extensive north-south range along the west coast, while P. balsamifera has a northerly range across the continent from Alaska to the North American east coast. Both species are well suited for highly productive bioenergy biomass plantations in north-temperate climates. We are investigating the large reservoirs of natural genotypic and phenotypic variation in wild populations of these species, with an initial focus on P. trichocarpa, to identify allele variation underlying optimal biofuel and biomass traits that could be used for accelerated domestication. We sampled genetic variation in P. trichocarpa by Illumina transcriptome resequencing of 20 individuals from provenances along a latitudinal gradient from 67°N to 44°N. This analysis revealed extensive identity, gene expression and alternative splicing polymorphism in 10,000 xylem-expressed genes. Alignment of transcript sequences to the P. trichocarpa Nisqually-1 reference genome was used to identify over 500,000 SNPs. These SNPs were combined with a larger SNP set generated by whole genome resequencing of multiple P. trichocarpa individuals carried out by the US DOE Bioenergy Sciences Center (BESC) to populate a P. trichocarpa SNP database. Using the Illumina iSelect process, we generated an Illumina Infinium bead array for genotyping of 34,000 SNPs that tag 3,700 candidate genes selected for their potential involvement in biomass, adaptation, and wood traits. Using this bead array in collaboration with BESC, we obtained candidate gene SNP genotypes for over 700 P. trichocarpa individuals grown in common gardens. This analysis of these data revealed extensive genotypic polymorphism in the targeted gene set. In parallel, we carried out phenotyping of the trees from the wild populations grown in common gardens, quantifying variation in over 85 morphological, growth, physiological, wood chemistry, and wood quality traits. Population genetic analysis of the SNP data, its use for genotype-phenotype association studies to identify candidate gene alleles underlying variation in traits of interest, and the prospects of using the results for marker assisted breeding will be discussed.

**03 Lodgepole pine, jack pine, and their hybrids: molecular markers reveal mountain pine beetle host-range expansion into jack pine of the boreal forest**

BMC Proceedings 2011, 5(Suppl 7):O3

Background: Lodgepole pine (Pinus contorta Doug. ex Loud. var. latifolia) and jack pine (Pinus banksiana Lamb.) is a closely related species found east of the Rockies, mainly in Canada’s boreal forest from the Northwest Territories to Quebec [1]. Lodgepole and jack pine ranges overlap in northern Alberta and the Northwest Territories, where these species hybridize (Fig. 1). In the absence of reliable molecular markers, morphological characteristics are commonly used to distinguish lodgepole pine, jack pine and hybrids. However, hybrids and pure species can be difficult to visually distinguish, particularly at the presumed periphery of the hybrid zone, which is poorly described. Mountain pine beetle (MPB; Dendrocutrus ponderosae Hopkins) is indigenous to western North America. In the current MPB outbreak, more than 14 million hectares of mainly lodgepole pine forests have sustained MPB-caused mortality in British Columbia alone [2]. Following MPB long range dispersal into northwestern Alberta in 2006, MPB has continued its apparently unprecedented eastward spread into the lodgepole x jack pine hybrid zone of Alberta (Fig. 1).

To better define this hybrid zone, we developed microsatellite and SNP markers that distinguish the pure species from hybrids. We then used the microsatellite markers to test the hypothesis that the MPB epidemic has spread into jack pine.

Materials and methods: Foliage was collected from 678 trees representing 25 localities in British Columbia, Alberta, Saskatchewan, Ontario, and Minnesota in 2007, 2008 and 2010, including 154 MPB-attacked trees from British Columbia and Alberta. Eleven microsatellite markers amplifying both lodgepole and jack pine were developed from published loci [3] and loci isolated from a microsatellite enriched (GT,) x CT,) lodgepole pine library. Genotyping and scoring was carried out as described [4]. There were less than 2% missing data, with a 0.0% genotyping error rate. Loci met Hardy-Weinberg equilibrium criteria; pairs of loci in linkage disequilibrium were negligible. Genetic diversity measures were calculated in GENEPOP [5], GenAlEx [6] and HP-RARE [7]. Assignment tests were conducted in NEWHYBRIDS [8] and STRUCTURE [9]. In silico species-discriminating SNP detection was carried out using CLC Genomics with lodgepole and jack pine cDNA 454 sequence data, and validated with PCR.

Results and discussion: Genetic diversity was high among localities, and was higher in lodgepole than jack pine. Differentiation among localities (FST = 0.125) and between species (FST = 0.133) was high. Within species, differentiation among localities was generally lower (FST = 0.033, FSTjack = 0.016). The efficacy of the microsatellite loci to distinguish pure species and hybrids was tested by assignment of individuals to their correct class with NEWHYBRIDS and STRUCTURE, using five simulated datasets (ten iterations each) containing multiple levels of admixture generated with known pure lodgepole and jack pine as benchmarks. Using 0.7 greater than or equal to 0.9 to assign pure species and 0.7 less than 0.9 to designate hybrids, we achieved accurate resolution of first and second generation hybrids in simulated datasets using both NEWHYBRIDS and STRUCTURE, but
Geographic shifts in climatically suitable areas and loss of genetic variability under climate change in a neotropical tree

BMC Proceedings 2011, 5(Suppl 7):O4

Background: Many species are expected to suffer a strong shift in geographic ranges due to climate changes in the next fifty years, depending on their ecological tolerance and current demographical parameters, which were in turn shaped by their evolutionary history. These shifts may also cause a change in genetic population structure and variability, because local extinctions or reduction in fitness are not expected to be random in geographical space. Here we used an ensemble forecast approach of Species Distribution Modeling (SDM hereafter, also known as niche modeling) to derive current and future geographic distribution of the Neotropical tree Dipteryx alata (‘Baru’ tree, Fabaceae). We then obtained a series of genetic parameters for the
species after generating extinctions in areas of low future habitat suitability.

Methods: We obtained a total of 448 occurrences of *D. alata* throughout the Brazilian Cerrado, which were recorded in a grid with 6240 cells of 0.5° of latitude/longitude covering South America. These occurrences were modeled as a function of eight climatic variables (WORLDCLIM), for the current time and projected into 2050, for three different Global Circulation Models (AOGCMs - CCCma, Csiro, HadCm3) [1,2]. Occurrences were modeled using six different SDM techniques [3]. Methods used were BIOCLIM, Euclidian, Gower and Mahalanobis distances, GARP and MAXENT. For each of these methods, models were built using 255 combinations of the climatic variables, each one tested using 50 cross-validations using True-Skill statistics (models with TSS < 0.7 were excluded). A Principal Component Analysis (PCA) of the estimated frequencies of occurrence, obtained by SDMs and AOGCMs, was used to compare the maps. Variance components of these sources were obtained and mapped [2].

Genetic data for *D. alata* consisted in microsatellites markers analyzed for 25 widely distributed local populations, encompassing species' geographical range. A total of 644 individual trees were genotyped for eight microsatellite loci. Genetic parameters were used to estimate the total amount of polymorphism and genetic diversity currently found in *D. alata*. We estimated the number of alleles per locus, genetic diversity (expected heterozygosity under Hardy–Weinberg equilibrium), and the expected

Figure 1(abstract O4) Shifts of climatically suitable areas in 2050 for *Dipteryx alata*, expressing change in estimated frequency of occurrences of the species based on six species distribution models projected into three GCMs.
heterozygosity under mutation-drift equilibrium. Moreover, we recalculated these parameters by assuming that, under climate change, there will be a displacement of climatically suitable areas for the species and, consequently, that only populations found in regions above certain levels of suitability in the future will persist.

**Results and discussion:** The ensemble forecasting approach reveals that *D. alata* will shift its geographic range and climatically suitable areas from Central towards Southeastern Brazil (Fig. 1). The first principal component explains 74.3% of the variation among maps and, on average, 95% of the variation among them is due to SDMs used.

The changes in the climatically suitable areas in *D. alata* imply a reduction in the genetic parameters. The parameters remain approximately constant up to a 50% threshold, which is the minimum by assuming a major consensus of frequency of occurrences. However, after this critical threshold there is an abrupt reduction in all parameters, although the magnitude of shift is only about 10% of the current values, on average (Fig. 2). There is a wide variation of shifts direction and magnitude among loci for each parameter, and actually these trends are usually driven by two or three loci.

The wide current range and ecological tolerance of *D. alata* explains why low levels of loss in genetic diversity were observed here, contrasting with previous results for other species (i.e., the “pequi” tree *Caryocar Braziliense*). Because of the wide range, currently and in the future, some of the local populations with highest genetic diversity will potentially remain in highly suitable areas in the future, even using very conservative thresholds of 80%. However, it is important to highlight that coalescence analyses and the expected heterozygosity under mutation-drift equilibrium suggest strong population bottlenecks for the species in the recent past, which were corroborated by hind cast projections of the SDMs using paleoclimatic data. This explains the low level of genetic variability in *D. alata* despite its wide geographic range.

Thus, despite the shift in geographic range size and climatically suitable areas towards Southeastern Brazil and the expected downward shift in the genetic parameters, the analyses performed here do not show a strong loss of genetic diversity in *D. alata*. Even so, it is important to realize that these results are mainly due to the relatively low current genetic variability of the species, probably associated with recent population bottlenecks. In this case, climatic shifts can have more serious adaptive consequences and further investigations are necessary to avoid a false indicative of high probability of persistence of this species based on a low relative level of loss of genetic diversity.

**05 Genomic signatures of selection in response to sulfate air pollution in natural populations of red spruce**

Om Rajora, Stanislav Bashalkhanov

Faculty of Forestry and Environmental Management, University of New Brunswick, 28 Dineen Drive, Fredericton, NB E3B 5A3, Canada
E-mail: Om.Rajora@unb.ca

**BMC Proceedings** 2011, 5(Suppl 7):O5

Rapid environmental changes, such as anthropogenic air pollution, can create significant evolutionary pressures on populations, species and ecosystems. Evolutionary processes occurring in natural populations at very short time scales, especially in response to human-induced environmental changes, are not well understood. Confounding effects of geographic variation and demography cannot be easily separated from signatures of recent selection in natural populations. We investigated the genetic response of declining red spruce (*Picea rubens*) populations at high elevation sites in Southern Appalachians to anthropogenic sulfate depositions. Red spruce seedlings are more sensitive to drought and cold stresses elicited by exposure to anthropogenic sulphate air pollution, than old trees. Genetic variation in seedlings and young trees was significantly reduced in heavily polluted stands. Several candidate genes involved in cold acclimation and calcium metabolism demonstrated signatures of selection corresponding with sulfate pollution levels. SNP allele frequencies at one gene involved in calcium metabolism demonstrated directional selection in response to...
anthropogenic sulfate deposition in red spruce growing at severely polluted high elevation sites, which correlates well with the putative role of this gene in adaptation to acidification stress. Unlike range-wide experimental designs (e.g. the popular FST outlier test) and nucleotide diversity-based association studies, our within-population testing approach disentangled the confounding effects of geographic variation and demography from the genetic effects of recent selection.

**06. Effects of forest fragmentation on the effective and realized gene flow of Neotropical tree species: implications for genetic conservation**

Alexandre Sebbenn
Instituto Florestal de São Paulo, Brazil
E-mail: alexandresebbenn@yahoo.com.br

Tree species are key organisms of forest ecosystems, due their size and extended life, providing the environmental setting for many other living organisms. The levels of genetic diversity and the effective population sizes are essential issues for the maintenance and survival of tree species populations, because they directly adapt to the current environment and future environmental changes. Forest fragmentation around the world is a fact, affecting many animal and plant populations in all continents. In Brazil, forest fragmentation and selective logging are the two main problems affecting populations of tropical tree species. For example, the Atlantic Forest was intensively destroyed and fragmented during the last century. Today, only between 11 and 17% of the original areas remain, generally split into small forest fragments or isolated trees in pastures and agricultural lands. In the Atlantic Forest, only 3% of the original area of the Araucaria Forest biome in southern Brazil remains. Forest fragmentation is especially drastic in tropical forest biomes, due to the very high species diversity, associated to low population density (<1 tree/ha). Thus, after forest fragmentation takes place, the remaining fragmented forest may contain the same species diversity, but the populations are strongly reduced, and, in some cases, less than a dozen reproductive individuals remain. The bottleneck (size reduction of the reproductive population) caused by forest fragmentation associated to spatial isolation of the remaining stands may cause the loss of genetic diversity, an increase in inbreeding and relatedness, reducing the effective population size and blocking seeds and pollen migration inside the stands. These hypotheses have been tested in some tropical tree species of the Araucaria Forest and semicidual Atlantic Forest, including Araucaria angustifolia, Copaifera langsdorffii, Myracrodruon urundeuva and Hymenaea stigonocarpa, using microsatellite markers and parentage analysis. More specifically, in these studies we tried to answer the following questions: Can spatial isolation of tree populations following forest fragmentation block seed and pollen migration (gene flow)? What is the distance and patterns of seed and pollen dispersal in populations of tree species living within fragmented stands? Is there intra-population spatial genetic structure (SGS) in the adults and regeneration, and where is it higher, in adults or regeneration after forest fragmentation? Can forest fragmentation really reduce the genetic diversity and effective population size and increase the inbreeding and relatedness within populations? What is the necessary number of seed trees to collect seeds aiming at ex situ conservation and environmental reforestations plans with a reference effective population size that provides a minimum evolutionary potential? Knowledge of these issues is crucial to delineate strategies for in situ and ex situ conservations, tree breeding and environmental restoration plans. As many tropical trees are long lived individuals, established before forest fragmentation had occurred (<100 years), seeds, seedlings and juveniles, established after forest fragmentation have been included in the samples. Thus, these studies have been based on the sampling of all reproductive trees regenerates (realized seed and pollen dispersal), as well as open-pollinated seed (effective pollen dispersal). All adult trees and regenerates were also counted and the diameter at breast height (dbh) and/or total height measured and in the case of dioecious species, all reproductive trees were also sexed. We used a set of microsatellite loci to arrive to a high exclusion power, to guarantee that each candidate parent displays a unique multilocus genotype for parentage analysis. Our results showed an essentially perfect isolation of seed gene flow, with total absence of seed immigration, probably due to the large distance separating the remaining forest fragments, associated to an intensive use of surrounding land (agriculture, highways, urban areas, etc.). Within populations, although long distance seed dispersal events were detected, seeds generally disperse intensively near the mother trees following a classic isolation by distance model. These hypotheses have also been supported by studies of SGS in both adults and juveniles and mating system, revealing significant rates of mating among relatives. In contrast, substantial realized and effective pollen immigrations have been detected in the studied species (ranging from 4 to 10%), evidencing longer-distance pollen dispersal than seed dispersal. Within populations, although the estimates are downward biased due to a substantial rate of pollen immigration in the stands, pollen generally disperses with high intensity at short distances, in a near neighbour pollen dispersal pattern, determined by the individual flowering patterns and behaviour of pollination vectors. Matings are not random, due to selfing, mating among relatives and correlated mating, resulting in higher inbreeding relatedness and lower effective population size in open-pollinated seeds than expected under a panmictic model. High inbreeding and relatedness and lower effective population size were also seen in the regeneration. Lower genetic diversity has been found in seeds, seedlings and juveniles when compared to the adult population, suggesting the occurrence of genetic drift. Taken together our results in the targeted species has indicated a requirement to maintain the genetic connectivity among the forest fragments using strategies of reforestation in riparian areas and forest corridors. Our results also suggest the need to collect seeds from a large number of trees for ex situ conservation, tree breeding and environmental reforestation, due to a typically limited effective population size contained in open-pollinated individuals. This small number of species studied so far does not represent all the genetic, demographic, reproductive and ecological characteristics of the tree diversity in the Atlantic Forest. To provide a stronger support to our hypotheses and results to date, new studies of gene flow, mating system, SGS, genetic diversity and effective population size are underway with other species. Finally, it is never enough to reiterate the importance of conserving tropical tree diversity for future generations so that they can benefit from them as we currently do. Although, in situ conservation is the indicated method for this purpose, conserving not only the target species, but also other organisms in the same biome using ex situ strategies is also necessary due the continued fragmentation and degradation of the Atlantic Forest.

**S2. LINKAGE AND ASSOCIATION MAPPING**

**07. Genetic dissection of transcript, metabolite, growth and wood property traits in an F2 pseudo-backcross pedigree of Eucalyptus grandis × E. urophylla**

Maria Magdalena van Dyk1, Anand R K Kullan1, Estchar Mizrachi1, Charles A Hefer1, L’Zanne Jansen van Rensburg1, Timothy J Tschaplinski2, Katherine C Cushman1, Nancy E Engle1, Gerald A Tuskan3, Nicoletta Jones1, Arnulf Kandler1, Alexander A Myburg1

1University of Pretoria, Department of Genetics, Forestry and Agricultural Biotechnology Institute (FABI), South Africa; 2Biosciences Division, Oak Ridge National Laboratory, USA; 3Sappi Forests Research, South Africa
E-mail: daileen.vandyk@up.ac.za

Background: E. grandis is used extensively for the production of pulp and paper due to its rapid growth, good form and ease of vegetative propagation. E. urophylla exhibits tolerance to fungal diseases that limit the growth of E. grandis in tropical and subtropical regions. Interspecific hybrids of these two species are, therefore, commonly used to produce fast-growing, disease tolerant hybrids for eucalypt plantations in tropical and subtropical regions (e.g. South Africa, Congo and Brazil). These hybrids often exhibit superior growth and wood quality compared to the pure species, but the underlying genetic basis of the observed hybrid superiority remains unclear. Phenotypic variation observed in interspecific mapping populations has been used to identify QTLs in several genetic linkage studies in Eucalyptus. However, QTL intervals have generally been wide (20 to 30 cm) and may include several hundred
genes. To bridge the gap between fine mapping and QTL validation studies, the expression levels of genes and metabolites in individuals from the segregating population can be treated as quantitative traits and used for eQTL and mQTL mapping, respectively. Co-localization of wood property, expression and metabolite QTLs will facilitate the identification of positional candidate genes and other components of regulatory networks underlying phenotypic variation.

Methods: To identify genetic factors controlling growth and wood property traits in *Eucalyptus*, an F$_2$ pseudo-backcross mapping family derived from a cross between an F$_1$ hybrid (GUSA1, *E. grandis* x *E. urophylla*, Sappi Forest Research) and an *E. urophylla* parental (USAP1), consisting of 555 individuals, was used for genetic linkage map construction using microsatellite and DArT markers. Phenotypic trait assessment included physical measurements of tree diameter and wood density performed on 319 three-year-old individuals. Klassen (acid-soluble & insoluble) lignin and cell wall sugar content were determined for a selection of 100 backcross progeny and used for near-infrared analysis (NIRA) calibration. NIRA predictions for glucose, xylose, arabinose, cellulose and total lignin content, as well as pulp yield were made for all 315 individuals. Total lignin and S/G ratios were also separately measured for the 315 individuals. Immature xylem tissues, collected from 192 backcross progeny, were used for metabolite profiling (ORNL, Oak Ridge, TN) and Illumina mRNA-Seq (PESO, BGI Americas) quantification of transcript levels.

Results and discussion: Parental genetic linkage maps were constructed for the F$_1$ hybrid (GUSA1, *E. grandis* x *E. urophylla*) and the *E. urophylla* backcross parent (USAP1, Kullan et al. submitted). An integrated parental linkage map, constructed using the cross pollinator (CP) population type in JoinMap®4, was used for QTL mapping as this allows for the detection of the effect of alleles inherited from a single parent and the interaction between the alleles inherited from both parents. In addition to more than 50 growth and wood property trait QTLs (physical measurements, NIRA predictions and wood chemistry traits) and more than 80 metabolite QTLs (mQTLs), representing variation in 22 known metabolites, we will present progress made towards the mapping of gene expression QTLs (eQTLs) based on mRNA-Seq profiling of the first 96 backcross individuals in the dataset.

Conclusions: high-density genetic linkage maps, as constructed during this investigation, enable the accurate identification of genomic regions harbouring QTLs, mQTLs and eQTLs. This is an on-going investigation in which we will integrate different genomics data with the aim of dissecting regulatory networks underlying growth and development in *Eucalyptus*.

Methods: Linkage analysis and QTL analysis were conducted in 650 individuals from four separate pedigrees; a clonally replicated outbred F$_2$ family grown on a single site (112 genotypes), and three F$_3$ families (180 individuals each) grown at two additional widely separated sites. Trees were assessed for growth, wood density, cellulose content, pulp yield, klassen lignin content and the syringyl:guaiacyl (S/G) ratio of lignin, at 7 years of age. Chemical traits were estimated using NIR spectroscopy [1]. Saturated linkage maps were constructed in each family, predominantly from Diversity Array Technology (DArT) markers [2] as well as some SSRs, candidate genes and AFLP markers using Joinmap. Common markers were used to construct a consensus map of all families which was used for the QTL analyses. QTL analyses were conducted at various levels (across all families and sites combined, in each family and in each family by site combination) in order to investigate the stability of QTL expression across families and sites.

Results and discussion: Ninety eight QTL were detected across all analyses, of which 87 affected wood properties and 11 affected growth. QTL for several different chemical wood properties were co-located, consistent with their high phenotypic correlations. Several of the QTL detected co-located with previously reported QTL in *E. nitens*, *E. globulus* and *E. grandis* [3-5] and candidate genes including COBRA [5,6], and CCR [4]. Major QTL were also identified in regions of the genome where no candidate genes or QTL had been previously mapped. Nineteen of the QTL were significant in more than one family, and therefore were re-validated. These validated QTL would be the priority for searches for positional candidate genes in the genome sequence of *Eucalyptus grandis*.

Significant QTL by environment interaction was found for 17 out of the 98 (17%) wood property QTL and for 5 out of 11 (45%) growth QTL. This was consistent with significant family by site interactions exhibited across these sites, particularly for growth. The higher level of QTL by environment interaction for growth compared to wood properties was consistent with quantitative genetic studies in the genus [7]. Nevertheless, there was a surprising proportion of wood property QTL (including validated QTL) which were expressed on one site, but not the other within the same family. While there are few multi-site QTL or association mapping studies in forest trees, in most such studies high levels of QTL (or SNP) by environment interactions have been found [8,9].

Conclusions: Comparative mapping demonstrates that the genomes of commercially important eucalypt species (within Symphyomyrtus) are highly syntenic and co-linear (e.g. Hudson in prep), suggesting QTL results may be applicable across eucalypt species. It is therefore important to use transferable markers such as DArTs and SSRs to facilitate comparison of QTL results between studies. Considering the findings of this and previous QTL studies in the genus, growth and wood properties appear to be highly polygenic. Several of the QTL detected co-located with previously reported QTL in *E. nitens*, *E. globulus* and *E. grandis* and also with some well characterised wood property candidate genes. However, the specificity of many QTL to particular families and sites in this study reinforces the importance of considering the effect of site and genetic setting may complicate the application of marker assisted selection (MAS) or genomic selection.

BMC Proceedings 2011, 5(Suppl 7):O9

Background: This research explores the universality of genetic variation in genes controlling wood formation across the genus Eucalyptus. Breeding and deploying Eucalypts for improved wood quality is constrained by the delay before wood traits can be measured reliably. Manual assisted selection (MAS) offers a way to make earlier selection of wood properties, by selecting Single Nucleotide Polymorphisms (SNPs) in the DNA which can predict specific phenotypic traits (genotype-phenotype links). SNPs shared between species (trans-specific SNPs) may have broad application to multiple species. When the species are more distantly related, ancient SNPs shared between subgenera (trans-subgeneric SNPs) are likely to be of adaptive importance and persist in separate lineages due to balancing selection [1].

Sample and methods: The focal species of this investigation was Eucalyptus pilularis of the subgenus Monocalyptus, one of the most important species for solid wood production in Australia. As part of the development of suitable SNP markers for E. pilularis, two other important species were included for comparative purposes. The first comparison was made with the closely related Eucalyptus pyrocarpa, which grows in parapathy with E. pilularis and is distinguished by minor morphological characteristics including a larger leaf and capsule size [2]. More distant comparisons were made between both Monocalyptus species and the alternate Symphyomyrtus subgenus, represented by Eucalyptus globulus subspecies globulus. DNA was pooled from 30 individuals representing the natural geographical range of each of three species. A total of 34 genes were amplified from each pool and sequenced on an Illumina GAIlx. SNPs were identified in individual species pools and classified as trans-specific if they shared the same reference position in two or more species.

The association study focused on E. pilularis and utilized 561 destructively sampled trees from a nine-year-old progeny trial established by Forests NSW at Hannam Vale, near Port Macquarie in New South Wales, Australia (Latitude 31°40', Longitude 152°33'). This sample represented the genetic diversity of 284 open-pollinated families, collected across 37 provenances that encompassed a large part of the natural distribution of this species. We tested 40 traits covering growth, wood chemistry (lignin, cellulose, hemi-cellulose complexes), and wood dimensional stability, strength and stiffness [3]. Eight SNPs were genotyped in pectin methylesterase 6 and 7 (PME6 and 7) using Sequenom iPLEX gold chemistry. Association testing was performed using a General Linear Model (GLM) in TASSEL where 1,000 permutations were applied. Kinship between family members was a problem and was addressed by the inclusion of a kinship matrix as covariate data within the model. The large population size used allowed for validation of results in smaller subsets of the population containing only single representatives from each family. Previous studies have reported no geographical population structure for the provenances included in the breeding program [4].

Results and discussion: Among the three species 6,852 SNPs were identified in total. Pairwise comparisons between species representative of divergent subgena revealed that 20-23% of SNPs were shared. These trans-subgeneric SNPs are likely to have persisted in separate lineages for tens of millions of years following the split of the Monocalyptus and Symphyomyrtus subgena and may be indicative of adaptive variation maintained by balancing selection [5]. The primary signatures of balancing selection were significantly higher proportions of trans-subgeneric SNPs in exons and promoters, compared to introns and 3' untranslated regions. Further analysis revealed that ten of the 34 genes investigated were likely to be influenced by balancing selection with a significantly higher proportion of trans-subgeneric SNPs and high nucleotide diversities. PME6 and PME7 were two of the genes considered likely to be influenced by balancing selection. Association testing revealed several significant correlations between SNPs in these genes and solid wood properties of E. pilularis. PME6 was primarily associated with shrinkage of drying timber. This is consistent with a role for pectin as a hydrophilic polysaccharide, and patterns of methyl-esterification are known to affect the water holding capacity of pectin gels. PME7 was primarily associated with cellulose and pulp yield, and inversely with lignin content. Selection of specific alleles in these genes may enable identification of trees with superior wood quality for breeding and deployment. For some SNPs, the heterozygote was superior, indicating that selection to fix one allele in the breeding population would not be appropriate. In combination with haplotype blocks, a heterozygote advantage at one or more PME7 loci may explain the absence of one homozygous class at all SNPs investigated in this gene. Alternatively the absent homozygous genotypes may be disadvantaged during early life stages.

Conclusions: Using comparative genomics we provided direct DNA-based evidence that many candidate genes for wood formation are under balancing selection and therefore of adaptive importance. Such knowledge of genetic variation maintained by balancing selection could be critical to ensure that selection for alleles linked to desirable phenotypes does not compromise the maintenance of adaptability in the breeding population. This concept needs to be tested, and our experiments provide a number of suitable markers which could provide the basis for further investigation. Each of these informative SNPs in both PME genes could be used for MAS, subject to cost-benefit analysis. Given the large number of trans-subgeneric SNPs identified in these genes, many informative SNPs are likely to transfer to other species, facilitating the development of SNP markers in other commercial species within the diverse Eucalyptus genus.

BMC Proceedings 2011, 5(Suppl 7):O10

We present results of two large scale comparative studies of the genomic basis of resistance of interior spruce to the white pine weevil.
Both volume growth, the main objective of the spruce breeding program in British Columbia, and white pine weevil resistance, are examined. "Interior spruce" is a species complex involving mainly *Picea glauca* (White spruce) but introgressed with *P. engelmannii* (Englemann spruce), depending upon locality. In the first study, we compared constitutive expression of 17825 genes between 20 resistant and 20 susceptible trees to the weevil, 54 upregulated and 137 downregulated genes were found in resistant phenotypes, with implications discussed in regard to volume growth. In particular, we will be surveying these genes for SNPs that differ between these two classes of trees in the next year. In the second study, we developed a 1536 Illumina SNP chip based upon candidate genes for weevil resistance. In a novel experimental design, we assayed 945 open-pollinated progeny of the Prince George breeding population (176 parents), and 654 open-pollinated progeny of the Prince Rupert breeding population (134 parents); parents were also genotyped. Within each family of 100 progeny, we identified the highest ranked 3 progeny and the lowest ranked 3 progeny, based upon BC Ministry of Forests scores for volume growth and resistance. These were genotyped and used in a novel test analogous to the transmission disequilibrium test to detect both SNP associations and QTLs linked to SNP markers. Discoveries about associations and QTL are discussed, with the added caution about genotyping error. Both studies illustrate how operational tree breeding populations can provide valuable inferences about tree genomics.

**BMC Proceedings** 2011, 5(Suppl 7):O11

**Background:** *Eucalyptus* trees (family Myrtaceae) are well-known for their high foliar content of several classes of secondary metabolites and these have a strong effect on the feeding patterns of several species of marsupials and at least some insects. Best known are the essential oils, which is mostly a mixture of terpenoids, but there are also significant concentrations of flavonoid and formylated phloroglucinol compounds. There is extensive quantitative and qualitative variation within and between species of *Myrtaceae* in these chemical groups and all appear to be under strong genetic control with heritabilities ($H^2$) between 0.3 and 0.9. As well as being important ecologically, the terpenes in particular are valued as industrial and medicinal products and Australia supports a strong essential oil industry focused on *Eucalyptus* and *Melaleuca* foliar oils.

**Results and discussion:** The *Eucalyptus grandis* genome provides the opportunity to discover the genetic makeup of the biosynthetic pathways for secondary metabolites. We present data from pathways leading into the biosynthesis of terpenes, flavonoids and lignins. The homology of genomes and gene families were investigated and compared to a variety of other species including *Populus trichocarpa*, grape (*Vitis vinifera*) and apple (*Malus x domestica*). For example, terpene synthases (the gene family responsible for the final step in the terpene biosynthesis) has 120 members in the genome of *Eucalyptus grandis*, compared to 44 and 99 in poplar and grape, respectively (Table 1). Genes of the biosynthetic pathways for secondary metabolites were mapped to the *Eucalyptus grandis* genome and their location was compared to a number of quantitative trait loci (QTL) studies that investigated variability in secondary metabolites and wood properties in eucalypts. This approach allowed the discovery of candidate genes for a large number of QTL. Understanding the genetic basis of variations in quantitative traits provides insights into ecosystem function and at the same time may help breeders in the essential oil industry. We have characterized trait associations with polymorphisms from *Eucalyptus globulus*, investigating 200 SNPs and roughly 40 traits ranging from terpenoids to terpene-adducts to flavonoids and to tannin-related traits. We discovered several significant trait associations between allelic variants in the chloroplastic MEP pathway and monoterpenes and between the cytosolic MVA pathway and sesquiterpenes, as well as one allelic variant in a prenyl pyrophosphate synthase that associates with the ratio of monoterpenes to sesquiterpenes. Loci with significant associations were mapped to the *Eucalyptus grandis* genome and compared to published QTL datasets that investigated similar traits. These results represent the first species wide analysis of the molecular basis of quantitative variation in secondary metabolites in any tree.

**Conclusions:** The publicly available genome sequence of *Eucalyptus grandis* is a great resource that can be applied to a variety of questions including the genetic make-up of gene families for biosynthesis of plant secondary metabolites, genome organization of these genes and evolution of traits such as resistance to herbivores or the ability to re-sprout after fire. Combining studies of association genetics, QTL studies together with the genome sequence helps to shed light on the underlying control mechanisms of phenotypic variation.

Lignin quantity and composition are major components of wood quality in eucalypts breeding programs. Optimizing these traits can have a huge economical impact for charcoal and pulp production. However, little is known about the genetic determinism of these traits. Our objective is to establish efficient early selection criteria to identify ideotypes for these traits using gene based markers. To reach this goal, we first estimated genetic parameters for lignin quantity and composition using a factorial design comprising 16 founders and 328 progenies of *E. urophylla*. We found high heritability for both Klassen Lignin (h²=0.85) and Syringyl to Guaiacyl ratio (S/G: h²=0.62). Then, nucleotide and haplotype diversities were described for two linked genes involved in the lignification process (CCR and ROP1). High levels of nucleotide diversity and rapid decay of linkage disequilibrium were observed in a sample of 16 trees. A SNP by SNP association mapping was carried out in the 328 progenies using a mixed linear model (available in Tassel). A total of 4 SNP (3 in CCR and one in ROP1) were significantly associated with S/G ratio explaining between 1 and 1.8% of the trait variation. Finally, the additive effects of haplotypes (defined by all SNPs) were estimated using a Bayesian approach of the mixed model including the pedigree (MMCMCggmm package available in R software). This analysis confirmed the existence of two distinct additive effects for CCR and ROP1 on S/G ratio, suggesting the existence of two S/G QTLs for these two linked genes in *E. urophylla*.

S3. GENOMICS ASSISTED BREEDING

O13 Genomic selection in tree breeding: testing accuracy of prediction models including dominance effect
Marie Denis*, Jean-Marc Bouvet
CRABD - Research unit 108 “Breading and adaptation of tropical and Mediterranean plants”, International campus of Baillarguet TA A-39/C, 34398 Montpellier, Cedex 5, France
E-mail: marie.denis@crab.fr

Background: The concept of Marker Assisted Selection (MAS) is rapidly evolving in animal and plant breeding. With the advent of high throughput molecular technology, numerous molecular markers distributed throughout the whole genome can be produced to characterize many genetic entries involving new perspectives in methodology of selection. An important research activity has begun in the animal world given the first theoretical framework for a methodology called genomic selection (GS) [1]. Several statistical approaches have been proposed for the prediction of genomic breeding values and numerous results are available that validates the interest of this method in animal breeding. In plants the GS is still limited to very advanced model species involved in genetic improvement and especially from scenario-based simulation [2,3].

In tree breeding the GS could significantly reduce the cost of genetic improvement schemes by limiting the size and number of field experiments; and facilitating the early selection at the nursery stage [4]. If most of the studies on GS have addressed the prediction of breeding value, taking into account the gene additive effects, there is still a lack of analyses dealing with the total genetic value (genotypic value) including both additive and dominance effects. This aspect is important in plant and especially in tree breeding where the goal of some programs is the production of clones or elite families. The aim of this study is to investigate the performance of GS in the context of tree breeding when the selection is based on genotypic value. The proposed approach allows taking into account both additive and dominance effect [5] for each marker in the statistical model. Six scenarios are simulated to test the reliability of the GS in the frame of recurrent selection scheme.

Methods: Simulation: The data used to evaluate the accuracy of the model have been simulated using HaploSim package in R software [6]. Firstly, populations were simulated for 1000 generations at an effective size of 100 to reach a mutation-drift balance. Fifty parent trees were then selected to start a breeding scheme that was conducted during two generations. At each generation, a progeny test was performed using a factorial mating design. The fifty percent parents were selected and crossed according to a factorial design to constitute the following generation. At each generation, 670 individuals issued from the mating of 16 females and 34 males were evaluated for clonal selection. The 670 individuals were genotyped for 400 SNP markers equally-spaced across one chromosome of one Morgan corresponding to an efficient marker density.

The broad sense heritability $H^2$ was equal to 0.3. A gamma distribution was used to sample the 44 QTL effects. The additive (breeding), dominance and genotypic values were simulated for each individual. The ratio of dominance to additive variance was equal to 0.1, 0.5 and 1. Six scenarios were evaluated for predicting the genotypic value: three different ratios and two different QTL distributions (high proportion with small or medium effects).

Analysis model: Genomic selection consists in following steps: (i) estimation of the effects of all markers in a ‘training data set’, where the individuals are phenotyped and genotyped; (ii) prediction of the genetic values of other ‘evaluation’ individuals by combining their marker genotypes with the estimates obtained in step (i).

A Bayesian implementation of the Lasso method with BLR package in R [7,8] was used to estimate the substitution and dominance effects for each of the 400 SNP. This method allows predicting the genotypic value using all markers simultaneously with different variances for each marker effect. We evaluated the performance of the statistical model with and without dominance effects. The training and validation set corresponded, respectively, to the first and second generation containing each 670 individuals. The criterion to compare the different scenarios was the accuracy calculated as the correlation between true and predicted genotypic value.

Each simulated data set and analysis was replicated 30 times.

Results: The accuracy of two models decreases when the ratio of dominance to additive variance increases whatever the QTL distribution (table 1). In all scenarios GS is superior to basic phenotypic selection. In addition, the model with dominance effects shows a higher accuracy, especially when the variance ratio increases. For the second generation the same trend is observed but the model with dominance effects is more accurate when the ratio of variances is greater than 0.5. A lower accuracy is observed in the second generation; it can be attributed to the low linkage disequilibrium of this breeding population two generations after selection in simulated wild population.

Conclusions: The model including dominance effects is more accurate to predict the genotypic value especially when the dominance-additive variance ratio increases. These results are particularly interesting for tree improvement in hybrid populations where dominance effects are marked and clonal varieties are produced (eucalyptus, poplar, for example).

Background: A tree breeding program is characterized by long generation intervals which, over time, result in a much smaller number of breeding cycles when compared to annual crops. Moreover, most economically important traits in a tree-breeding program are quantitatively inherited, display low heritability and are expressed late in the life cycle. Genomic Selection (GS) is expected to be particularly valuable for tree species, leading to shorter generation intervals and improved genetic gain over time.

The main factors that affect the accuracy of GS prediction models are the level of linkage disequilibrium (LD) in the training population, the training population size, the heritability of the trait and the number of QTL regulating its variation. However, it is yet largely unknown how stable prediction models are across environments and different ages. This knowledge is critical for tree breeders that wish to use genomic selection in their genetic improvement program.

Here, we report the first assessment of the utility of genomic selection in a conifer species. We developed prediction models for growth traits measured at multiple sites, to evaluate the impact of genotype by environment interactions in their accuracy. Training populations were also measured over multiple ages and models were developed to assess their value in predicting breeding values later in the lifecycle.

Material and methods: Here we analyzed a population of 790 to 840 individuals of loblolly pine, clonally replicated in four sites in the southeastern US: Palatka and Nassau (Florida, USA), Cuthbert and B.F. Grant (Georgia, USA). The population is derived from 61 full-sib families, established by crossing 32 parents in a circular mating design. The traits analyzed in this study were diameter at breast height (DBH) measured when trees were three, four and six years old; and total height (HT) measured when trees were one, two, three, four and six years old. All the individuals were genotyped with a total of 3,938 SNPs [1]. Single marker regression association analyses were initially performed treating the markers as fixed effects. The markers that were selected in this association analysis had their effects estimated adjusting all the allelic effects simultaneously using a genomic BLUP procedure [2]. These analyses were performed across all sites, traits and ages and the estimated effects of the markers were validated using a 10-fold cross validation approach. The selection gain of genomic selection was compared to classical phenotypic selection considering a reduced breeding cycle due to early selection.

Results and discussion: The accuracies of the prediction models for GS developed using phenotypic data measured in each site at year 6 ranged from 0.65—0.75 for DBH, and 0.64—0.77 for HT. To evaluate the performance of GS relative to traditional breeding methods, we estimated the accuracies of BLUP-based selection [3] and used it as a benchmark for the comparison of the accuracies obtained by GS. The increase in efficiency per unit of time in the selection response of GS was 53—95% higher for DBH, and 58—118% higher for HT, assuming a conservative reduction of 50% in the length of the breeding cycle.

To evaluate if models generated at early ages would predict well the phenotype at mid-rotation, we assessed the accuracy of models developed for HT based on data collected at ages 1 to 4, but validated with measurements from the same populations at age 6. Accelerating model estimation is beneficial because the sooner models that accurately predict phenotypes at rotation age can be developed, the faster genomic selection can be adopted. However, the models developed for HT early in the rotation (age 1 to 3) had limited accuracy in predicting phenotypes at age 6.

Next, we tested the suitability of models estimated in each individual site, in predicting phenotypes across different sites. The accuracies reduced up to 86% (Table 1) and the decrease parallels the increase in geographic distance between the site for which models were estimated, and the site where they were validated. Therefore, environment x genotype interactions appear to severely affect the transferability of models across breeding zones.

Out of the total number of markers, 177 and 83 were significantly associated with traits across all sites for DBH and HT, respectively. Those were selected for model estimation since they may reflect marker-trait associations that are independent, or at least less affected, by genotype x environment interactions. Initially, models were re-estimated based on data from each site, using only the subset of markers, and re-validated in the same site. Accuracies were only slightly lower (3—9% for DBH, 6—13% for HT) than those obtained when models included the full set of significant markers (Figure 2). Therefore, a significant component of the genetic variance appears to be captured by relatively few markers (>100).

Next, prediction models were estimated based on a combine-site model and validated individually in each of the four sites (Figure 1). While accuracies remained relatively high across sites (0.43—0.51 for DBH, 0.46—0.54 for HT), there is a decrease of up to 30% relative to the accuracy obtained when the full set of markers and site-specific specific data was used for model estimation (Figure 1). Therefore, while the same reduced set of markers is relevant for explaining the genetic variation in all sites, the magnitude of their effect changes significantly from site to site. In conclusion, the results in efficiency demonstrated that incorporating genomic selection would dramatically increase the genetic gains per unit of time of a conifer’s breeding program. Moreover, even at relatively low marker density, the accuracy of prediction models could significantly impact the genetic gain efficiency. However, the use of a prediction model should be constrained within a breeding zone once genotype x environment can affect the prediction and reduce the accuracy of those models.

Figure 1(abstract O14) Accuracy of genomic selection models estimated using the complete (black bar) or subset of markers significant across all sites (white and grey bars), or estimated based on a combined-site model and validated in individual sites (grey bar).

_BMC Proceedings_ 2011, 5(Suppl 7):O15

**Background:** The identification of polymorphisms that underlie complex phenotypic traits presents new and exciting challenges to molecular genetics. Association mapping, which uses linkage disequilibrium (LD) to map trait variation with nucleotide polymorphisms, has proved suited for this purpose in outcrossed tree species. Association mapping can be undertaken either at a candidate gene level or at the whole-genome level however; until sufficiently dense marker assays are developed the candidate gene approach will remain the most effective way of dissecting complex traits in tree species. To date, this approach has led to the identification of several quantitative trait nucleotides (QTN) that associate with a variety of breeding traits including, early wood specific gravity, percentage latewood [1], microfibril angle [2], cellulose [3] and carbon isotope discrimination [4].

**Aim:** Our research aims to identify single nucleotide polymorphism (SNP) markers using candidate gene-based association mapping that can predict growth and wood quality in _Eucalyptus globulus_.

**Materials and methods:** A _Eucalyptus globulus_ provenance-progeny trial, planted in 1989 near Latrobe in north-central Tasmania, Australia, by Gunns Ltd, was used as the association discovery population. An eight-year-old Southern Tree Breeding Association (STBA) breeding trial growing near Frankland, Western Australia, is being used for validating marker-trait associations. Twenty functional candidate genes for wood and fiber formation, were selected for this study. SNPs were discovered by direct sequencing of PCR products from 11 to 28 trees. The iPLEX Gold assay (Sequenom Inc.) was used to genotype 98 selected polymorphisms in up to 385 individuals from the discovery population. This subset includes individuals from eight races of _E. globulus_. Linkage disequilibrium (LD) was estimated using GEVALT [3] and Hardy-Weinberg equilibrium was estimated using FSTAT ver 2.93.2 [6] respectively. To account for genetic structure, 18 SSR markers were genotyped in all the discovery samples. Ancestry (Q) co-efficients were estimated using the model-based clustering method as implemented in STRUCTURE [7]. A matrix of pairwise kinship coefficients (_r_) was calculated as described in Ritland [8], using the program _r_ [9]. Marker-trait associations were tested using a mixed linear model (MLM) [10], which accounted for both population structure and familial relatedness using _TASSEL_ version 2.01 [11].

**Results:** At a 5% significance level, only 4 SNPs deviated from Hardy Weinberg expectations in more than one race. With all races pooled, LD between SNPs was very low with only 0.06% of the pairwise comparisons having _r_^2^ values greater than 0.33. Only where _r^2_ is greater than 0.33 is there sufficiently strong LD to be useful for association mapping [12]. Only one pair of SNPs, EgCA2_4186_ and EgMYB2_1380 between genes was found to be in LD (r^2^ > 0.5). When LD was computed within races 1.3 to 2.7% of the pairwise comparison had _r_ values greater than 0.33. Of the 98 polymorphisms tested against 12 traits, 33 associated significantly (P < 0.05) with one or more traits giving a total of 62 associations. Individual polymorphisms explained between 0.9 and 3.8% of the phenotypic variation observed. Marker-trait associations found in the discovery population are currently being validated by testing their consistency using the validation population.

**Conclusions:** Candidate gene based association mapping studies are a useful means of dissecting complex quantitative traits in species like _E. globulus_ with low LD and high nucleotide diversity. This study, like other tree association mapping studies, shows that the percentage of phenotypic variation explained by a single polymorphism will often be small. This is not unexpected because of the complex nature of most wood quality traits. The small proportion of the phenotypic variation explained so far using association mapping should not detract from its future use in tree breeding, since genotyping costs are expected to fall while throughput increases, thereby facilitating larger scale association mapping efforts in the near future.

_BMC Proceedings_ 2011, 5(Suppl 7):O16
Background: Genomic selection (GS) involves selection decisions based on genomic breeding values estimated as the sum of the effects of genome-wide markers capturing most QTLs for the target trait(s). GS is revolutionizing breeding practice for complex trait in domestic animals. The same approach and concepts can be readily applied to forest tree breeding. Trees also have long generation times and late expressing traits. Differently from association genetics that aims at dissecting complex traits in their discrete components, GS precludes the discovery of individual marker-trait associations and focuses on prediction of performance. By capturing the “missing heritability” of complex quantitative traits beyond the few effect variants that association genetics has so far typically identified, GS might soon cause a paradigm shift in forest tree breeding. In a prior deterministic study we assessed the impact of linkage disequilibrium (modeled by Ne and inter-marker distance), the size of the training set, trait heritability and the number of QTL on the predicted accuracy of GS [1]. Results indicate that GS has the potential to radically improve the efficiency of tree breeding. The benchmark accuracy of conventional BLUP-based phenotypic selection (0.68) was reached by GS even at a marker density ~2 markers/cM when Ne ≤ 30, while up to 10 markers/cM are necessary for larger Ne. Shortening the breeding cycle by 50% with GS provides an expected increase ≥100% in selection efficiency. To validate these simulation results we carried out a large multipopulation proof-of-concept study of GS in tropical Eucalyptus. In this report we present results of this on-going study for two populations and three different quantitative traits.

Methods: This study was carried out in two structured populations of Eucalyptus represented by two progeny trials of independent breeding programs. The first was a progeny trial developed by CENIBRA (CEN) with 43 full-sib families generated by an incomplete diallel mating design carried out by intercrossing 11 highly selected E. grandis × E. urophylla hybrids clones therefore having an effective population size of Ne= 11. The second population was a progeny trial installed by FIBRIA (FIB) with 232 full-sib families involving 120 elite parents, the vast majority F1 hybrids of E. grandis, E. urophylla, E. globulus and E. maidenii. For the CEN study however only the most phenotypically relevant 75 families were used derived from intercrossing 55 parents therefore limiting the effective population size to Ne= 55. A sample of trees was taken in a stratified way from all families to provide a balanced representation of all families with similar numbers of individuals per family. Bark or leaf samples were collected, DNA extracted and genotypes obtained for 783 and 920 trees from CEN and FIB respectively. Genotyping was carried out using a high-throughput genotyping platform developed earlier [2]that provided 3,120 and 3,564 robustly scored dominant DArT markers. De-regressed phenotypes for Height (H), Diameter at Breast Height (DBH), wood density (WD), pulp yield, lignin content and Puccinia rust resistance were obtained. Single marker regression association analyses were initially performed with all the traits, treating the markers as fixed effects. Markers selected in the previously described analysis had their effect estimated adjusting all the allelic effects simultaneously using Random Regression Best Linear Unbiased Predictor. Each population was then divided in a training set comprising 90% of the total number of individuals and a validation set with the other 10%. The estimated effects of the markers were validated using a cross validation approach using random sub-sampling with ten replications so that all individuals had their phenotypes predicted by GS. Details of the overall analytical approach have been described [3,4].

Results and conclusions: To date results have been obtained for height, DBH and wood density while the remaining traits are under analysis. Realized accuracies by Genomic Estimated Breeding Values (GEBV) for H and DBH were 0.67 and 0.69 for CEN and 0.62 and 0.54 for FIB while for WD in FIB it was 0.53. These accuracies match or surpass those obtained by conventional BLUP (Best Linear Unbiased Prediction) based phenotypic selection. Not surprising GEBV accuracies were low (~0.18) across populations implying variable genotype-phenotype associations across backgrounds so that population-specific GS models will be necessary. GS-based reduction in breeding time by 50%, i.e. by reducing a breeding generation time from 12 to 6 years should provide gains ≥100% in selection efficiency. If a reduction from 12 to 3 years using flower induction can be achieved, gains in selection efficiency theoretically could surpass 300%. These are among the first experimental results of GS in forest trees and in plants in general. With the technological advances and declining costs of genotyping methods we anticipate that GS will soon be implemented operationally and revolutionize Eucalyptus tree breeding practice.

inter-species polymorphism between Ec and Eg. In addition, 75 insertions and 90 deletions within Ec and eight intra-specific deletions in comparison to Eg were detected. After appropriate corrections as described, the ‘useful’ SNP number reduced to 1,191 which was ~10.5% of the original SNP count (~frequency of 1 per 84.5 bp). Table 1 describes findings from the present analysis of SNPs. A total of 198 putative EF blocks containing 541 SNPs, grossly comparable to LD blocks, with 55, 65 and 34 in exons, introns, exon-intron junctions respectively were detected (rest all were small in numbers) with an average length of ~105 bp (SD: ±182; range: 1-1234 bp, distribution shown in figure 2; ~3 SNPs/block) and would aid in selection of SNPs. The comparable mean lengths adjusted for the respective amplicon lengths were around 0.014 to 0.016 (SD: ±0.013 to ±0.015) for exons, introns and nongenic regions whereas for intron-exon junctions it was 0.028±0.023, significantly longer than the rest (p=0.03).

Conclusions: Herein, NGS (Illumina) platform was successfully used for identifying ~1,200 SNPs in 41 targeted genes in Ec which has shed important light on quantitative and qualitative distribution of SNPs. In addition, the analysis of EF blocks also provided important guidelines for selection of SNPs for genotyping.

The European chestnut, Castanea sativa Mill, covers a total area of 2.53 million hectares two million of which are chestnut forests, i.e. forests where chestnut is the dominant tree species, being the remaining 0.53 million hectares devoted to fruit production (20.9% of the total chestnut-growing area). Chestnut fruit production in Europe declined considerably during the XX century to the current 200,000 t (almost 300 million euros). This decline arose mainly due to serious diseases and changes in the structure of society. Towards the end of the century, there was a sharp increase in chestnut demand which triggered new planting and the restoration of old orchards throughout Europe, although ink disease (Phytophthora spp.), canker blight (Cryphonectria parasitica (Murrill) M.E. Barr) and more recently Dryocosmus kuriphilus Yasumatsu, still represent major threats to the species. In Europe, chestnut breeding has been focused on the improvement of cultivars and rootstocks through selection and hybridisation with Asian species resistant to ink disease. Considerable success was obtained using this approach, however little information was acquired until now on the genetic basis of resistance in chestnut.

A set of interspecific crosses were established between European chestnut and Asian species and two separate full-sib pedigrees have been produced, SC (C. sativa x C. crenata) and SM (C.sativa x C. mollissima). The goal is to perform DNA markertrait association analysis to identify QTLs related to ink disease resistance and also to identify quantitative resistance genes to P. cinnamomi using a transcriptomic approach. An overview of the study will be presented including the genotyping of the mapping population (parents and progenies) with nuclear SSR markers designed for Castanea mollissima and provided by the American team of Fagaceae Genomics Project, for the construction of the first genetic linkage map. The methodologies implemented for the determination of the metrics of resistance of mapping population, for further identification of QTLs, will also be presented.

O19 Sequence-based breeding: application to unravel traits of the 6F crops: food, feed, fiber, flowers, fuel and fun
Mark van Haaren
Keygene Inc, the Netherlands
E-mail: mvh@keygene.com

BMC Proceedings 2011, 5(Suppl 7):C19

The genomes of the world’s most important crop species differ enormously in size, ploidy levels, repeat composition and germplasm diversity, posing a tremendous challenge to utilize them for breeding and trait improvement. Keygene’s Crop Genome Center addresses this challenge by developing and applying sequence-based methodologies to advance building genome assemblies and elucidating genetic diversity of 6F crops. For example, novel strategies to build very high quality genome sequence assemblies make use of our Whole Genome Profiling (WGP) technology and high parallel local sequence assemblies. For sequence-based genotyping we developed random Sequence-Based Genotyping (rSBG), a technology which incorporates the high-throughput sequencing capacity of the Illumina Genome Analyzer (GA-II) and the genome complexity reduction capabilities of AFLP®. rSBG allows for simultaneous sequence-based marker discovery and detection and is therefore a highly suitable technology for cost efficient, highly flexible, sequence-based genotyping, not requiring prior sequence information and custom reagents. These technologies, together with KeyGene’s lead discovery and molecular mutagenesis platforms, significantly increase the rate with which the genetic basis for (complex) traits can be unraveled. In this presentation, I will present recent applications of these technologies in our breeding research programs.

The AFLP®, Whole Genome Profiling and rSBG technologies are covered by patents and patent applications owned by Keygene NV. AFLP® is a registered trademark of Keygene N.V.

O20 The regulation of quantitative variation of foliar terpenes in medicinal tea tree Melaleuca alternifolia

BMC Proceedings 2011, 5(Suppl 7):O20

Background: Terpenes are important mediators of plant-environment interactions as well as often being economically important. Terpenes are biosynthesized via two spatially separate pathways: the MEP pathway in the plastid, the site of monoterpen biosynthesis and the MVA pathway in the cytosol, the site of sesquiterpene biosynthesis (McGarvey and Croteau 1995; Eisenreich et al. 1998; Rohmer 1999). Studies using transgenic plants have demonstrated that when the MEP genes dks and ddx and MVA pathway gene hmgr are up-regulated plants exhibit an increase in foliar terpene concentrations (Chappell et al. 1995; Wildung and Croteau 2005; Carere-Paulet et al. 2006). However, the importance of the expression of these genes has not been demonstrated for naturally occurring quantitative variation in foliar terpene concentrations.

Aims and methods: Melaleuca alternifolia(medicinal tea tree) is a small tree in the family Myrtaceae that is grown in plantations for its valuable terpene-rich leaf oil. We studied the expression of MVA and MEP pathway genes to identify those that are correlated with variation in foliar terpene concentration. Diagnostic primers were designed for seven MEP pathway genes, three MVA pathway genes and three genes downstream of both pathways. Transcript abundance for all 13 genes was then quantified from 48 individuals on the Fluidigm biomark platform.Foliar terpene concentrations were determined by GC of ethanol extracts containing an internal standard.

Results: Foliar terpene concentration varied from 5 to 12.2% of dry matter (DM), terpinen-4-ol concentration from 48 individuals on the Fluidigm biomark platform. Foliar terpene concentrations were determined by GC of ethanol extracts containing an internal standard.

The transcript abundance of five genes within the MEP pathway were correlated significantly with variation in foliar terpinen-4-ol concentrations. The transcript abundance of three MEP pathway genes and one MVA pathway gene were significantly correlated with foliar bicyclogermacrane (the most abundant sesquiterpene) concentrations. However, the expression of the genes within both pathways were co-dependent and showed strong pair-wise correlations within pathways. Therefore, multiple regression models were formulated to account for interactions amongst the genes. A multiple regression model using only the genes in the MEP pathway explained 87% of variation in foliar terpinen-4-ol concentrations (Figure 2). A multiple regression model of the genes within both the MEP and MVA pathways explained 60% of variation in foliar bicyclogermacrane concentrations (Figure 2). Two sub-models using only the genes from either pathway explained significantly less variation in bicyclogermacrane concentrations than the full model (MEP only, r2 = 0.5; MVA only, r2 = 0.15) and indicated that both pathways contribute to the...
pool of isopentyl pyrophosphate (IPP) used to biosynthesize bicyclogermacrene.

Discussion: Several studies have shown that the expression of dxr and dxs has a strong influence on foliar terpene yield; however, this has only ever been demonstrated in transgenic plants and never on naturally occurring, quantitative variation in terpene concentrations. Our results show that a large proportion of the quantitative variation of foliar terpene concentration in M. alternifolia can be explained by quantitative variation of transcript abundance of genes in the early stages of terpenoid biosynthesis. A number of MEP pathway genes are correlated

Background: Bud development is an adaptation that temperate forest trees have acquired to survive inclement winter conditions and resume growth the following spring. Bud development is a complex physiological and developmental process comprising bud formation, cold and desiccation tolerance development, and dormancy acquisition [1]. Because bud formation is accompanied by growth cessation, the timing of bud formation represents a trade-off between acquisition of winter hardiness and duration of active growth [2]. This is particularly true for determinate species such as white spruce (Picea glauca [Moench] Voss), where preformed stem units contained within the apical bud constitute most of next season’s growth. Timing of bud set in white spruce shows genetic variation [3]. Our goal is to identify genes that exert genetic control over time to bud set in white spruce. As first steps towards that goal, we have conducted microarray gene expression profiling of shoot tips during the transition from active growth to dormancy in white spruce, and identified candidate regulators of bud formation by comparing these differentially expressed (DE) genes to results obtained from QTL analyses of time to bud set conducted using the same genes as molecular markers.

Materials and methods: Two year old white spruce nearing completion of active growth were placed in either short day (SD; 8 h days / 16 h nights, 20°C) or extended long day (LD; 16 h days / 8 h nights, 20°C) photoperiods, and samples harvested at 0, 1, 3, 7, 14, 28 and 70 d. After an additional 8-15 weeks in SD, plants were transferred to low temperatures (LT) under continued SD for 3-4 weeks prior to final harvest. Light microscopy, microarrays, SYBR Green qRT-PCR, and hormone analyses were conducted as described [4].

Results and discussion: Unlike determinate species such as Populus spp., white spruce does not require environmental cues such as reduced photoperiod or cooler temperatures to initiate bud formation, although these cues may be required to complete bud development and acquire endodormancy. However, SD hastens and synchronizes bud formation. To reduce biological variation, we conducted most analyses with seedlings under SD. Microarray analyses revealed 4460 DE genes in shoot tips during SD-induced bud formation. These analyses revealed the timing of molecular processes that occur during bud formation, identifying DE groups of genes associated with meristem transitions, identity and maintenance; organogenesis; protein synthesis and turnover; chromatin assembly and remodeling; cell wall biosynthesis and expansion; carbohydrate and lipid metabolism; secondary metabolism; and general stress responses. Changes in gene expression correlated with anatomical changes occurring at the shoot apex during the transition from active growth to endodormancy. Comparison of DE genes in developing buds under SD and LD uncovered ca. 2000 genes that are DE under both photoperiods at comparable phases of bud formation. This common set of genes is likely important for bud formation, particularly during early stages. Many genes DE shortly after transfer of plants to SD are likely photoperiod-responsive but not essential for bud formation. Genes DE only under SD at later stages of bud formation could be involved in processes associated with completion of bud formation and transition to endodormancy, events which do not appear to occur fully under LD. Further comparison of shoot tip, needle and stem transcript abundance profiles during this time course revealed approximately 100 genes that are DE only in developing buds and show greater transcript abundance in developing buds than other tissues. Several genes DE during bud formation – including some genes both preferentially expressed and only DE in buds – are putatively associated with hormone signalling. Quantification of ABA, cytokinins, auxin and their metabolites during SD-induced bud formation revealed distinct profiles for these hormones during bud formation, with shifts in hormone levels coinciding with morphological events such as bud scale development. A small number of genes DE in developing buds fall within QTL regions identified for time of bud set [5]. Some of these genes also show signatures of selection in natural populations of white spruce via identification of Fst outliers [6]. These candidate genes may exert genetic control over time to bud formation, and are currently being studied in more detail An eQTL experiment and association study are underway to identify additional candidate regulators of time to bud set.

Conclusions: This comprehensive study of gene expression changes that occur at the shoot apex during the transition from active growth to dormancy in white spruce has revealed timing of processes critical for overwintering preparation, and groups of genes implicated in these processes. Use of these same genes as molecular markers in QTL analyses has enabled us to tentatively identify candidate genes that may exert genetic control over the time of bud formation in white spruce. These results provide new insight into an important adaptive trait, and lay the groundwork for more detailed studies into regulators of time of bud set in conifers.

Summary: Although there have been many observations of transgenes leading to improved plant growth in greenhouse experiments, there is a paucity of data that have been validated by multiple greenhouse experiments or field studies. Genes that encode regulators of gibberellin metabolic pathways were among the first reported to improve biomass growth in trees, and thus were the logical focus of this study. Poplars were transformed with eight different transgenic constructs designed to modify gibberellin biosynthesis and/or signaling. Dramatic improvements in growth rate were observed for several constructs under greenhouse conditions. However, these were often not seen in repeated greenhouse studies, and were statistically unconfirmed for most constructs in the field. Our results underline the importance of multiple greenhouse and field trials during studies with transgenes that modify hormonal homeostasis.

Genes studied: The genes under investigation in this study were GA20-oxidase, PHOR1-1, and SPINDLY. GA20-oxidase catalyzes the conversion of C20-gibberellins to C19-gibberellins through a series of sequential oxidation steps using 2-oxoglutarate as a co-substrate [1]. This enzyme was first isolated from pumpkin cotyledons [2], and is involved in the penultimate step in the production of bioactive gibberellins. The PHOR1-1 gene is a positive regulator that was first isolated from leaves of potato plants subjected to a short day photoperiod (SD) [3]. Altered feedback regulation was observed in transgenic plants produced by antisense inhibition of this gene, indicating the role of the PHOR1-1 protein as an intermediate in the gibberellin signaling pathway. SPINDLY (SPP) is a gene that codes for an O-linked N-acetylgalactosamine transferase [4]. In Arabidopsis, it has been shown to inhibit GA signaling, and thus is considered a negative regulator of GA signaling [5].

Methods: Combinations of the three different genes and seven different promoters were used (Table 1). In addition to constitutive promoters, we used native promoters of poplar genes which were identified by screening whole-genome microarray expression data. Plants transformed with all eight constructs were grown in the greenhouse, while those transformed with six of these constructs were also grown in the field. For four constructs, the greenhouse trials were repeated at least once. In all, 2,066 trees were studied in the greenhouse (286 independent transformations) and 556 trees (94 independent transformations) were studied in the field. Transgenic and non-transgenic controls were included in both the greenhouse and field studies. Height and diameter measurements were recorded in both the greenhouse and the field, and shoot and root biomass were measured on the greenhouse-grown plants. Levels of bioactive gibberellins were also measured on a subset of plants transformed with the two cisgenes (a gene having driven by its own promoter and ending with its own terminator), as well as in plants that had the RGL and the GA2-oxidase promoters driving the PGa20-oxidase gene.

Results and discussion: When considering the best growth rate improvements for constructs that had repeated greenhouse trials, the maximum growth rate improvement seen (the mean of the best two events relative to the control) varied from 50 to 220% i.e., a fractional growth rate improvement ranging from 0.5 to 2.2 (Figure 1). However, results were not consistent between the different greenhouse trials. The best events showed more than 100% in maximum growth rate improvement (fractional growth rate improvement > 1) in six different greenhouse experiments (Fig. 1); however, these events did not have a similar extent of improvement when the experiments were repeated. Five out of eight constructs produced a statistically significant improvement in growth rate (Figure 1).

Only one out of the six constructs tested in the field produced a statistically significant improvement in volume index, and this was for the RGL promoter driving the PGa20-oxidase gene. The GA20-oxidase and the PHOR1 cisgenic plants, when grown in the greenhouse, had substantial increases (73-133%) in the levels of bioactive gibberellins in developing shoots compared to control plants, however, there was no significant correlation between gibberellin levels and volume index of each event. The levels of the gibberellin biosynthetic precursors were also measured and found to be greater than the bioactive gibberellin level, suggesting feedback inhibition—a possible mechanism for the lack of association with growth. Our results suggest that physiology-modifying transgenes strongly interact with growth environments. This implies that, as in conventional plant breeding, greenhouse results are of limited value and field trials are essential for evaluation of varieties with improved productivity.

We have shown that the cambial cell division activity, and thus, the wood development is of great importance for future use of tree products as a renewable resource. For this purpose, we have performed a detailed analysis of cytokinin function in the regulation of cambial development in a tree stem. Furthermore, we have identified potential cytokinin signaling response genes active during the secondary development in Arabidopsis and currently studying the best candidate genes also in Populus.

**Results and discussion:** In the cambium, expression of cytokinin receptor genes peaks in the actively dividing cells. This indicates that cytokinin signaling pathway is a major regulator of cambial cell proliferation. We have previously shown in transgenic Populus trees that we can slow down the cambial activity by reducing the level of cytokinin signaling in it [1]. To study if cytokinin signaling is truly a rate-limiting process for cambial activity, we have now engineered transgenic Populus trees with an enhanced cambial cytokinin signaling level. In these trees, we were able to see that elevated cytokinin signaling stimulated the cambial cell division activity and led to increased biomass production. Furthermore, based on microarray profiling in Arabidopsis, we have been able to identify several transcription factors functioning downstream of cytokinin signaling during the secondary development. These transcriptional regulators have stimulatory effect on radial growth in Arabidopsis root. We are currently studying if the Populus orthologs of these genes have similar function in the cambium of the tree stem.

**Conclusions:** We have shown that the cambial cell division activity, and through it the production of stem biomass, can be enhanced or decreased through elevated or decreased cytokinin signaling. Together, our results show that cytokinins are major rate-limiting hormonal regulators of cambial development. Our study provides potential for applied research towards future breeding of faster growing tree cultivars.

---

**Conclusion:**

- Enhanced cytokinin signaling stimulates cell proliferation in cambium of Populus
- Introduction: Understanding the regulation of radial growth that underlies wood development is of great importance for future use of tree products as a renewable resource. For this purpose, we have performed a detailed analysis of cytokinin function in the regulation of cambial development in a tree stem. Furthermore, we have identified potential cytokinin signaling response genes active during the secondary development in Arabidopsis and currently studying the best candidate genes also in Populus.
- **Results and discussion:** In the cambium, expression of cytokinin receptor genes peaks in the actively dividing cells. This indicates that cytokinin signaling pathway is a major regulator of cambial cell proliferation. We have previously shown in transgenic Populus trees that we can slow down the cambial activity by reducing the level of cytokinin signaling in it [1]. To study if cytokinin signaling is truly a rate-limiting process for cambial activity, we have now engineered transgenic Populus trees with an enhanced cambial cytokinin signaling level. In these trees, we were able to see that elevated cytokinin signaling stimulated the cambial cell division activity and led to increased biomass production. Furthermore, based on microarray profiling in Arabidopsis, we have been able to identify several transcription factors functioning downstream of cytokinin signaling during the secondary development. These transcriptional regulators have stimulatory effect on radial growth in Arabidopsis root. In addition to the SCW phenotype, *wat1* was characterized by S-Me-tryptophan seedling toxicity, severely decreased auxin transport and content in stems, and massive down-regulation of auxin-related genes. These data led us to the conclusion that *WAT1* acts as an upstream regulator of SCW deposition in fibers, presumably through an auxin-mediated mechanism [2].

Bioinformatic analysis of *WAT1*, annotated as ‘homolog to a Medicago truncatula nodulin gene, MtNOD21’, suggested that *WAT1* encoded a putative transporter belonging to the Plant Metabolite Exporter family [3]. *WAT1* overexpression in *Xenopus* eggs showed that *WAT1* is plasmalemmal-specific, it shares structural similarities with bacterial amino acid transporters in that it consists of ten transmembrane domains encompassed within a tandem Domain of Unknown Function (DUF6).

To characterize *WAT1* function, we recently tested its capacity to transport tryptophan and/or auxin in both yeast and *Xenopus* oocytes. Neither *WAT1*-expressing yeast cells nor *Xenopus* oocytes were able to facilitate radiolabeled Trp import or export. However, we have been able to demonstrate that *WAT1* facilitates auxin import in both expression systems. These results clearly place *WAT1* among the ranks, along with PINs, AUX/LAXs and ABCB/MDR/Pgps, as a novel, bona fide auxin transporter in plants.

This study constitutes the first functional characterization of any of the 46 members of the *WAT1* gene family in *Arabidopsis* and our hope is that this discovery will help pave the way in identifying the functions of other family members. Moreover, the *wat1* mutant will be an ideal tool to address the question as to how auxin subcellular homeostasis plays a role in fiber SCW formation in *Arabidopsis*. Our current efforts to understand poplar *WAT1*-mediated auxin signaling in wood formation in trees will also be discussed.

BMC Proceedings 2011, Volume 5 Suppl 7

In Norway spruce, environmental conditions during the reproduction can greatly influence progeny performance. We found that the temperature during post meiotic meagametogenesis (zygotic embryogenesis) and seed maturation shift the growth cycle program of the embryos in the seeds, resulting in significant and long lasting phenotypic changes in the progeny. Traits that are affected include the timing of dehardenion and bud burst in the spring; leader shoot growth cessation in the summer, and bud set and cold acclimation in the autumn. All processes are advanced or delayed in correspondence with the temperature during female reproduction. Colder reproductive environment advance bud set and cold acclimation during autumn and dehardenion and bud burst during spring in their progenies. Temperature dependent difference in timing of terminal bud formation in identical clones was equivalent to a 4-6° latitudinal ecotypic difference. The progeny “remember” the temperatures and photoperiod prevailing during zygotic embryogenesis and seed maturation and this memory, affecting the climatic adaptation in this species, is an epigenetic phenomenon.

This phenomenon is not only of evolutionary significance but has clear practical implications. This memory can help the conifer to cope with the anticipated rapid change in climatic conditions. It will have importance for the deployment of seedlings produced in seed orchards containing clones that are translocated to warmer sites, and it may be used to produce seedlings that have specific adaptive properties. So, it is possible to produce distinct epitypes (ectotypes) in Norway spruce, however this type of long lasting effects is not well documented in other organisms so far.

The molecular mechanism behind this striking epigenetic memory phenomenon is not yet understood but transcriptional changes are clearly involved. In epigenetically different progenies, transcriptional analysis revealed that seedlings from full-sib families produced at different embryogenesis temperature under long and short day conditions differed. Supressive subtracted cDNA libraries revealed significant differences in their transcriptomes. Using qRT-PCR, microRNA pathways genes *PaDCL1* and 2 and *PaSSG3* as well as transposons related genes are differential expressed in the epigenetically different progenies with phenotypic differences in bud burst and bud set. MicroRNAs (miRNAs) are endogenous small RNAs that can exert epigenetic gene regulatory impacts. We have examined the possible role of miRNA in the epigenetic phenomena, and found that Norway spruce contained conserved miRNAs as well as a large proportion of novel non-conserved miRNAs. From concatenated small RNA libraries from seedlings from the same parents, originated from seeds developed in a cold and warm environment from a family with distinct epigenetic effects, contrasted to one from a family with little response, miRNAs potentially involved in this epigenetic memory was identified. Most of the miRNAs target unknown genes or genes with no known function. The expression of seven conserved and nine novel miRNAs showed significant differences in transcript levels in progenies with distinct epigenetic difference in bud set, but not in the progenies from a non-responder family, making them excellent candidate miRNAs. The differentially expression of specific miRNAs in genetically identical but epigenetically different progeny indicate their putative participation in the epigenetic regulation.

Epigenetic mechanisms influence phenotype through altered regulation of gene expression that is mitotically (and sometimes meiotically) propagated. Understanding the mechanisms involved in the initiation, maintenance, and heritability of epigenetic states is an exciting aspect of research in current biology. Epigenetic regulation may be realized through several interconnected molecular pathways including DNA methylation, histone modification and chromatin remodeling, small non-coding RNAs and transposable element regulation.

Among spruce ESTs we found 64 homologs of genes described as involved in DNA methylation, histone modification and chromatin remodeling and small RNA biogenesis in other plant species. In general, known epigenetic mechanism related genes are very well represented in the spruce genome.

We analyzed the transcription patterns of these genes using RT-PCR in epigenetically different zygotic embryogenic samples on different stages of development and in seedlings, originated from full-sib families clearly differed in epigenetic response. The largest difference in gene expression of selected genes was found at the earlier stages of embryogenesis while in seedlings a low number of these genes were differentially expressed. Most of the known epigenetic mechanism related genes in seedlings were steadily expressed in all studied samples independently of their epitype.

To get a deeper analysis of epigenetic related transcriptome we used high-throughput sequencing (RNA-seq and miRNA-seq) in cooperation with GenXPro GmbH. Using MACE (massive cDNA 3’end sequencing) deep miRNA sequencing on the Illumina GSFLX platform, we analyzed the genes differentially expressed in *P. abies* during early stages of embryonic development. We selected genes which could be involved into epigenetic response by comparison warm and cold originated “embryonic epitypes” from the same full-sibs family somatic embryos developed in cold (18°C) and warm (30°C) environmental conditions. Additionally, for more distinct epitypes we used a large amount of “no database hit” reads we sequenced one normalised library using 454 Titanium GS FLX sequencing to get reference transcript set of expressed genes. The sequencing data is currently under processing and we are going to discuss main results here.

To proceed with our initial study of miRNAs in spruce, we used Illumina/ Solexa sequencing to identify small RNAs expressed at the same epigenetic responsive family developed in warm and cold environment
progenies following short-day treatment. The identification of novel miRNA candidates are in progress and the confirmation of conserved and novel miRNA by qRT-PCR analysis will be presented.

O26 Dual function of auxin during leaf abscission in poplar
Xu Jin1,2, Urs Fischer2
1Swedish Agricultural University, Umeå Plant Science Centre, Department of Forest Genetics and Plant Physiology, Umeå, Sweden; 2University of Gottingen, Forest Botany and Tree Physiology, Gottingen, Germany

Background: Leaf abscission is an important trait for biomass production and seasonal acclimation in deciduous trees of the temperate region. Various plant hormones are involved in the timing of abscission. For example, ethylene signaling is required to induce hydrolysis of cell walls, while an auxin gradient [1] was suggested to act upstream of ethylene on the onset of leaf abscission. Besides pharmacological application of auxins on cut surfaces of explants, experimental evidence for such a gradient is however lacking. In addition to its function in temporal control, auxin has also been suggested to be a positional signal specifying the cells of the abscission zone [2].

Methods: We established an experimental system on intact Populus trees, which allows us to induce abscission synchronously under controlled conditions. Leaf blades were bagged in aluminum foil and abscission was recorded daily. Cumulative abscission followed a sigmoidal curve for dark-induced leaves, whereas control leaves in transparent bags of the same weight as the aluminum foil bags were not separated from the stem. Abscission was preceded by senescence in the petiole but not in the leaf.

Results and conclusions: Local auxin applications directly onto the abscission zone, as well as onto the distal end of the petiole, delayed dark induced abscission indicating that auxin could range not only as a short but also as a long distance signal. Similarly, an inhibitor of polar auxin transport retarded separation from the plant body. By contrast, auxin applied onto mature abscission zones only delayed abscission slightly in comparison to auxin applications before the development of an abscission zone. Taken together this points to a distinct function of auxin in early stages of abscission. Interestingly, we found shortly after dark-induction a new auxin response maximum on the abaxial side of the petiole, highlighting the incipient abscission zone. This auxin response maximum progressively moved from the abaxial to the adaxial side of the petiole, preceding the maturation of the abscission zone, presumably providing positional information for the formation of the abscission zone. Microarray data identified the auxin efflux carriers PIN1 and PINS, as well as a novel auxin transporter, to be down-regulated after dark induction. Immunolocalizations of those carriers will reveal if their subcellular localization and expression can explain the novel auxin response maximum.

O28 Integrative approach involving RNA-Seq, foliar traits and growth measurements revealed genotype-specific plasticity on Eucalyptus subjected to seasonal water shortage
Emilie Villar1,2, Christophe Plomion1, Jean-Marc Gion1
1INRA, France; 2INRA, France

Background: In the context of climate change, water availability will become an important limiting factor threatening biomass production, particularly in intensively managed forest tree plantations. The complexity of drought stress response calls for integrative approaches combining physiological, anatomical and molecular investigations at different scales ranging from particular cells to the whole plant. Such a strategy was developed for two eucalyptus clones used in industrial plantations in the Republic of Congo and known for their differences in term of productivity and water-use efficiency.

Methods: The two genetic units used in this study consisted in one more productive hybrid of *E. urophylla* × *E. grandis* (18-50), and one less productive hybrid obtained from open-pollination of *E. alba* (1-41). These genotypes were subjected to two watering regimes (irrigated during two dry seasons, versus non-irrigated) in open field conditions. Growth parameters such height, diameter at breast height, stem, leaf and root biomasses as well as physiological parameters, such carbon discriminationand specific leaf area, were regularly measured over two growing seasons. At the end of the second dry season (i.e. 14 months-old trees), polyphenols accumulation and anatomical measurements were performed on mature leaves. RNA of shoot apices from trees representing the four conditions (i.e. 2 genotypes subjected to 2 watering treatments) were extracted and used to create non-normalized libraries. Using 454/Roche sequencing, we performed digital expression analysis to highlight differentially expressed transcripts showing genotype, treatments and/or genotype by treatment interaction effects. Expression of candidates genes revealed by this first analysis were assessed by RT-qPCR on shoot apices and on mature leaves.

Results and discussion: Growth parameters and stem biomass analysis revealed that the two studied genotypes presented similar degrees of phenotypic plasticity in response to watering treatment during the

O27 Biomarkers and gene copy number variation for terpenoid traits associated with insect resistance in Sitka spruce: An integrated genomic, proteomic, and biochemical analysis of (+)-3-carene biosynthesis
Joerg Bohmann1,2, Wim Heuvelink1,3, Dawn Hall1, Jeanne Robert1, Christopher Keesing1, Dominik Domanski1, Alfredo Lara Quesada1, Sharon Jancsik1, Michael Kuzyk1,2, Michael Bohmer1, Christoph Borchers1
1Michael Smith Laboratories, University of British Columbia, Canada; 2University of Victoria – Genome BC Proteomics Centre, Canada; 3University of Victoria – Genome BC Proteomics Centre and Department of Biochemistry, University of Victoria, Canada

Conifers have evolved complex chemical defenses in the form of oleoresin terpenoids to resist attack from pathogens and herbivores. The large diversity of terpenoid metabolites is determined by the size and composition of the terpene synthase (TPS) gene family, and the single- and multi-product profiles of these enzymes. The monoterpene (+)-3-carene is associated with resistance of Sitka spruce (*Picea sitchensis*) to white pine weevil (*Pissodes strobi*). We used a combined genomic, proteomic and biochemical approach to analyze the (+)-3-carene phenotype in two contrasting Sitka spruce genotypes. Resistant trees produced significantly higher levels of (+)-3-carene than susceptible trees, in which only trace amounts were detected. Biosynthesis of (+)-3-carene is controlled, at the genomic level, by a small family of closely related (82-95% amino acid sequence identity) (+)-3-carene synthase (PsTPS-3car1) genes. Transcript profiling identified one PsTPS-3car gene (PsTPS-3car1) which is expressed in both genotypes, one gene (PsTPS-3car2) expressed only in resistant trees, and one gene (PsTPS-3car3) expressed only in susceptible trees. The PsTPS-3car2 gene was not detected in genomic DNA of susceptible trees. Target-specific selected reaction monitoring substantiated this pattern of differential expression of members of the PsTPS-3car family on the proteome level. Kinetic characterization of the recombinant PsTPS-3car enzymes identified differences in the activities of PsTPS-3car2 and PsTPS-3car3 as a factor for the different (+)-3-carene profiles of resistant and susceptible trees. In conclusion, variation of the (+)-3-carene phenotype is controlled by PsTPS-3car gene copy number variation, variation of gene and protein expression, and variation of catalytic efficiencies.

BMC Proceedings 2011, 5(Suppl 7):O28
dry season. Nevertheless, comparison of growth increments during wet seasons suggested that the more productive genotype had higher ability to recover from water shortage during the dry seasons and to use favorable conditions to increase its above-ground biomass. We found that the more productive genotype displayed greater plasticity of foliar traits in the non-irrigated treatment during the dry season, suggesting that it could adjust more quickly its leaf parameters when rainfall resumes. On mature leaves from trees subjected to water deficit, we identified mechanisms established to limit water losses by cuticle reinforcement and stomatal density decrease, to preserve leaf turgor by increase of collenchyma layer, to enhance hydraulic conductance with xylem vessel diameter decrease, and to preserve cells from reactive oxygen species through accumulation of hydroxycinnamates. Those adjustments were more intense for the more productive genotype, suggesting that this genotype may entail higher cost strategies to preserve its leaf functions.

On shoot apices, 454-sequencing provided a catalogue of 129,993 unigenes (49,748 contigs and 80,245 singletons) from the initial sequencing of 398M corresponding to 1.14Mreads. Digital expression analysis identified 1,280 contigs displaying differential expression between the two genotypes, 155 contigs between treatments, and 274 contigs displaying genotype x treatment interaction effects. The more productive genotype mainly under-expressed genes related to photosynthetic activity during the dry season, activating genes to reallocate resources through major changes in primary metabolism, whereas the less productive genotype displayed lower levels of variation in gene abundance between treatments. This analysis allowed to reveal a set of candidate genes that could be related to phenotypic variation observed in mature leaves.

Conclusions: The productivity of the two genotypes used in this study differed essentially in terms of ability to recover from water shortage. These differences could be explained by different strategies of investment in preservation of leaves. In the environmental gradient tested, it seemed that higher investments enabled genotype 18-50 to increase its leaf resistance, and subsequently to recover quickly high growth performance once environmental conditions become favorable. Genes that potentially underlie such physiological plasticity were revealed through integrative approaches. More investigations are now needed to validate their putative roles in phenotypic plasticity in response to water deficit. Forward genetic approaches could be used to screen the variability of gene expression and other more-integrated phenotypic traits, the nucleotide diversity of these candidate genes and their covariations on a larger genetic background.

O29 Influence of water deficit on the induced and constitutive responses of pines to infection by mountain pine beetle fungal associates
Adriana Arango-Velez, Miranda Meents, Jean Linsky, Waad El Kayal, Ari Adams, Leonardo Galindo, Janice Cooke
Department of Biological Sciences, University of Alberta, Canada

BMC Proceedings 2011, 5(Suppl 7):O29

Background: The ongoing outbreak of mountain pine beetle (MPB; Dendroctonus ponderosae Hopkins) and its associated pathogenic fungi (e.g. Grossmannia clavigera [Robinson-Jeffrey and Davidson] Zipfel, de Beer and Wingfield) in western North America has resulted in the loss of more than 13 million hectares of pine since 1999 in British Columbia alone [1]. MPB has principally attacked lodgepole pine (Pinus contorta Dougl. ex Loud. var. latifolia) in British Columbia. However, since 2006 MPB has spread into northern Alberta, where lodgepole pine hybridizes with jack pine (Pinus banksiana Lamb.) [2]. Few studies have compared lodgepole and jack pine defense responses, but given that lodgepole pine and MPB share a co-evolutionary history [1] whereas jack pine is a new host for MPB, differences could be explained by different strategies of investment in preservation of leaves. Some regions affected by the current outbreak have experienced drought conditions during the last decade. Water deficit can limit carbon assimilation, potentially increasing tree susceptibility to MPB and their symbiotic fungi [3]. We are testing the hypotheses that lodgepole and jack pine defenses against MPB and G. clavigera differ, and that water deficit affects these responses.

Materials and methods: The relationship between water availability and tree defense was evaluated in (1) two year old lodgepole and jack pine seedlings in growth rooms, and (2) ca. sixty year old lodgepole x jack pine hybrids in naturally regenerated, thinned stands. Soil relative water content was monitored using time-domain reflectometry. Seedlings were subjected to watering or water deficit for one week prior to woundng plus G. clavigera inoculation. Mature trees were either watered or water limited via tarps for six weeks before wounding plus G. clavigera inoculation. In both experiments, water deficit conditions were maintained throughout the time course. Tree physiological status was evaluated by measuring gas exchange and stomatal conductance using a LiCor 6400, stem hydraulic conductivity using a low-pressure flow meter and safranin dye xylem perfusion, and HPLC. Defense responses were assessed by lesion measurements histochemistry, and qRT-PCR.

Results and discussion: Stomatal conductance and photosynthesis significantly decreased under water deficit for both lodgepole and jack pine seedlings, but seedling hydraulic conductivity was not affected. The mild water deficit applied to the mature trees reduced stomatal conductance and photosynthesis, but not significantly. Stem lesions were a means of killing and compartmentalizing invading organisms [4]. G. clavigera-induced lesions developed more slowly in jack pine than lodgepole pine seedlings. Stem hydraulic conductivity decreased in inoculated lodgepole but not jack pine seedlings, likely because of greater tracheid occlusion caused by increased fungal growth and/or resin production in lodgepole pine [5]. Water deficit reduced lesion development rates at early time points in inoculated lodgepole and jack pine seedlings, as well as in mature trees at 5 weeks post-inoculation. Lesion length has been considered an indicator of tree defense capacity [6], with longer lesions reported to reflect increased release of toxic and/or inhibitory substances [7]. Accordingly, we interpret slower lesion development to indicate a slower defense response. Our results suggest (1) more rapid defense responses to G. clavigera in the co-evolved lodgepole pine host than in the new jack pine host, and (2) defense responses are slowed by water limitation.

We then examined the effect of water deficit on transcript abundance corresponding to genes classically associated with drought and defense responses. We conducted qRT-PCR transcript abundance profiling of secondary phloem from mature lodgepole x jack pine hybrids. We first profiled four aquaporin and five DREB genes, families associated with water stress responses. Although the mild water deficit did not significantly alter expression of these genes, expression of one aquaporin and one DREB decreased in response to G. clavigera inoculation. We then profiled five chitinase and four terpene synthase defense-associated genes. Expression of two chitinases was significantly induced by water deficit but not G. clavigera. Expression of other chitinases significantly increased in response to fungal inoculation, but the response was attenuated by water deficit. Expression of one terpene synthase significantly increased with fungal inoculation, but this response was also attenuated under water deficit. In contrast, water deficit increased constitutive expression of another terpene synthase. Higher constitutive expression of the monoterpene synthase under mild water stress suggests a pre-emptive defense via higher biosynthesis of volatile monoterpens. Microarray and qRT-PCR analyses of the lodgepole and jack pine seedling experiment are underway.

Conclusion: Our analyses suggest that defense responses of jack pine differ from those of lodgepole pine. Molecular analyses are underway to further characterize these differences. Both constitutive and induced defense responses are modulated in pines by water deficit, and this response appears to be gene-specific. This study shows evidence of cross talk between the water stress and defense responses of pine trees.

BMC Proceedings 2011, 5(Suppl 7):O30

Norway spruce [Picea abies (L.) Karst], is one of the economically most important conifer species in Europe. The major pathogen on Norway spruce is Heterobasidion parviporum (Fr.) Niemelä & Korhonen. The completed genome sequence of H. irregularae opens up new possibilities to understand the interactions between Heterobasidion spp. and spruce. However to date there are no completed genome sequencing projects of conifer genomes available for complementing studies. To achieve a better understanding of induced transcriptional defense responses in Norway spruce upon Heterobasidion spp. attack, we compared transcriptional responses in bark to H. parviporum infection to the response to wounding using cDNA-AFLP and transcriptome sequencing.

In an initial study bark samples were harvested at 3, 7, and 14 days post inoculation (dpi) and untreated bark was used as negative control. About 2500 transcribed derived fragments (TDFs) generated by cDNA-AFLP were screened. 199 TDFs were investigated further based on band intensity in the inoculated bark in relation to either untreated bark or wounded bark. Out of these, 119 TDFs had a putative homology and a consistent band intensity pattern between replications. A majority of these TDFs showed homology to genes known to associate with defense e.g. 3-deoxy-d-arabino-heptulosonate 7-phosphate synthetase (DAHP), Pathogenesis-related protein 1 (PR1), Lipoygenase (LOX), ACC-synthase (ACS), ACC-oxidase (ACO) and Jasmonate ZIM-domain 1 (JAZ1). Many of these are found in Salicaceae acid- or Jasmonic acid/ethylene-signalling pathways. The majority of the TDFs showed a similar expression pattern for all treatments but samples inoculated with H. parviporum generally showed an enhanced reaction (induction/repression) compared to wounded alone. Expression patterns were confirmed by qPCR in material treated with wounding and inoculation with H. parviporum or Phlebiopsis gigantea. Our data suggest that the infection with H. parviporum in Norway spruce induces a broad defense, with many similarities to non-specific defense responses in angiosperms. Additionally signs of reallocation of carbon from primary to secondary metabolism were evident.

With this information at hand we analysed four Norway spruce genotypes with either high or low susceptibility to Heterobasidion spp. [1] sampled 0, 5, 15 and 28 dpi with H. annosum. The bark phenol-composition was profiled in each sample. The 500,000 454-reads were assembled into 17,228 contigs that assembled in 14,364 putative transcript units (PTU) using the sequence assembler software Newbler** (http://www.454.com). The assembled reference file was annotated with the software Blast2Go and the PTUs were submitted to differential expression analysis. Data on associations between gene expression levels and phenol composition in bark upon H. annosum inoculation and level of susceptibility will be presented.

O31 Transcriptome sequencing of Eucalyptus camaldulensis seedlings subjected to water stress

Bala Thumma
CSIRO Plant Industry, Australia
E-mail: reddy.thumma@csiro.au
BMC Proceedings 2011, 5(Suppl 7):O31

Water stress limits plant survival and production in many parts of the world. Locus variation of genes responding to water stress conditions will underpin efforts to breed plants better adapted to drought. We studied the effect of water stress on Eucalyptus camaldulensis seedlings derived from three natural populations. Physiological and growth traits were measured and gene and allelic expression in leaves was examined by RNA sequencing (RNA-seq). Water stress had a significant impact on all the physiological and growth traits, while differences between the populations were not significant. Genes differentially expressed in leaves were identified by de novo assembly and by ab initio transcriptome mapping using the Eucalyptus grandis reference genome sequence. Gene ontology (GO) enrichment tests with 2,500 significantly differentiated genes revealed 128 stress-related gene categories were up-regulated while 28 gene categories belonging to photosynthesis and other metabolic processes were down-regulated under stress treatment. More than 190,000 single nucleotide polymorphisms (SNPs) and small indels were detected and 4,053 of these revealed differential allelic expression between control and drought stressed seedlings. Allelic expression of 70% of these variants was correlated with total gene expression. These variants may be cis-acting variants or in high linkage disequilibrium with such variants. The SNPs and indels identified in this study form a useful resource for further testing in association studies.

O32 The relationship between intra-specific variation in the Populus transcriptome, stomatal development, and the metabolome in response to drought

E-mail: erin.hamanishi@utoronto.ca

BMC Proceedings 2011, 5(Suppl 7):O32

Drought is one of the most significant factors limiting tree growth. Trees in the genus Populus are particularly noted for their drought sensitivity; therefore, understanding the mechanisms by which these economically and ecologically important forest trees respond to drought is of paramount importance. The ability of Populus trees to contend with drought is dependent on the responsiveness of the genome, and in turn, the ability of the transcriptome to appropriately remodel growth, metabolism and development. Amassing evidence indicates that different species of Populus have divergent mechanisms and adaptations to contend with drought stress; however, individuals within a given species also display divergent drought responses. In order to investigate the intra-specific variation underpinning the drought response, we examined six genotypes of P. balsamifera. Using Affymetrix Poplar GenChip, we found a positive correlation between the magnitude of drought-induced changes in the transcriptome and the capacity of the genotype to maintain growth. Surprisingly identifiable differences at the transcriptome were observed, and similar responses were observed within the metabolome. Although common drought responses could be identified within the species, the complexities of these responses must be taken into consideration when defining species- or genus-level drought responses.

New insights in the molecular events underlying actinorhizal nodulation in the tropical tree Casuarina glauca
Claudine Franche1, Didier Bogusz1, Maria Cecilia Gamboa2, Valerie Hoche1, Didier Bogusz1

1Rhizogene, Institut de Recherche pour le Développement, 911 avenue Agropolis, BP 64501, 34394 Montpellier Cedex 5, France; 2Laboratoire de Génétique, Biochimie et Biotechnologies Végétales, Département de Biologie et d’Ecologie, Université Montpellier, Route Ain El Bey, Constantine, Algérie
E-mail: claudine.franche@ird.fr

BMC Proceedings 2011, 5(Suppl 7):O33

Background: Actinorhizal root nodules result from the interaction between a nitrogen-fixing actinomycete called Frankia and roots of dicotyledonous trees and shrubs belonging to 8 plant families and 25 genera. Most actinorhizal plants are capable of high rates of nitrogen fixation comparable to those found in legumes. As a consequence, these trees are able to grow in poor and disturbed soils and are important elements in plant communities worldwide. This facility for adaptation has drawn great interest to actinorhizal plants, particularly to several species of Casuarinaceae such as Casuarina glauca, which can be used for fuel, food production, agroforestry, and land reclamation in the tropics and subtropics. The basic knowledge of the symbiotic association between Frankia and actinorhizal plants is still poorly understood, although it offers striking differences with the Rhizobium-legume symbiosis. Recently, the development of genomics in some actinorhizal plants such as C. glauca, together with the possibility to obtain transgenic actinorhizal plants following Agrobacterium gene transfer, has offered new approaches to understand the molecular basis of the actinorhizal process. We will highlight recent progress in the molecular knowledge of the early stages of the actinorhizal symbiosis. A comparative analysis of the symbiotic pathway in actinorhizal trees and legumes will be presented.

Methods: Plant material. Casuarina glaucaSieb. Ex Spreng seeds were obtained from B&T World Seeds (Aigues-Vives, France) and germinated in sterile conditions as described [4].

Genetic transformation of Casuarina glauca. Composite plants of C. glucawere obtained following the genetic transformation by Agrobacterium rhizogenes A4RS containing the appropriate binary vector [5]. For promoter analyses, binary vectors were derived from pBIN19 and for RNAi experiments, hairpin constructs were cloned into the pHKN29 vector using standard molecular methods.

Nodulation by Frankia. Composite and control plants were nodulated with a suspension of FrankiaC3.[4].

Results and discussion: CgSymRK is involved in the actinorhizal signal transduction pathway: The development of genetic and genomic tools for the model legumes M. truncatula and Lotus japonicus has greatly facilitated the cloning of genes required for root symbiosis [6]. Some of these genes were found to be involved in the establishment of both rhizobia and mycorrhiza symbioses, and designated as common SYM genes constituting the common SYM pathway. They include genes encoding a leucine-rich-repeat (LRR) receptor kinase (SymRK), cation channel regulator (CcAMK), and a calcium and calmodulin-dependent protein kinase (CcAMK) and a nuclear coiled protein. The question was raised whether some of these symbiotic genes were shared in the signal transduction pathway in response to Frankia factors and rhizobial Nod factors.

To answer this question, a functional study of CgSymRK, a gene isolated from C. glauca, homologous to the receptor-like kinase gene SymRK required for nodulation and mycorrhization in legumes, was undertaken. Downregulation of CgSymRK resulting from a RNA interference approach revealed that the frequency of nodulated RNAi-CgSymRK plants was reduced 2-fold compared to control C. glauca plants [7]. In addition, a range of morphological alterations was observed in the down-regulated CgSymRK plants. Additional experiments revealed that CgSymRK was also necessary for the establishment of the symbiosis with the arbuscular mycorrhiza Glomus intraradices. Therefore, the function of SymRK is conserved between legumes and actinorhizal plants.

Search for other candidates of the signalling pathway: Our group has developed the first genomic platform to identify plant genes involved in the symbiotic process between Frankia and C. glauca [2]. Based on the comparison with legumes sequences, ESTs sharing significant homologies with genes from the Nod signalling pathway were identified. Functional analyses of the candidate orthologues to the CcAMK and NIN genes are in progress. CcAMK is a calcium and calmodulin-dependent protein kinase that is presumed to decode and transduce Nod-factors specific calcium spiking response in legumes. Preliminary experiments suggest that CgCcAMK is necessary for both nodulation and endomycorrhization in C. glauca, thereby suggesting a conservation of the whole common SYM pathway in the actinorhizal plants.

Conclusion: Although several actinorhizal genera contain species that are economically important in forestry and land regeneration, progress has been slower in our knowledge of the actinorhizal symbiosis than that of the legume rhizobium interaction. The availability of a method for the genetic transformation of Casuarinas has resulted in a major breakthrough since it opened the way to functional gene analysis in the actinorhizal host plant. Deep sequencing analyses are now in progress in C. glauca and mining these data will undoubtedly to contribute to dissecting the molecular dialogue between Frankia and the host plant in the different stages of development of the actinorhizal nodule.

Potential use of the Eucalyptus globulus vacuolar pyrophosphatase 1 (EgEPV1) to generate drought and salt resistant plants
Erwin Krauskopf1*, Maria Cecilia Gambôa2
1Facultad de Ciencias Biológicas, Universidad Andres Bello, Santiago, Chile; 2Fundación Ciencia para la Vida, Santiago, Chile
E-mail: ekrauskopf@unab.cl

BMC Proceedings 2011, 5(Suppl 7):O34

Desertification is a phenomenon that affects vast territories worldwide usually caused by high soil salt concentrations, being salt and water stress one of the main problems that affect plant growth. Part of the strategy developed by the plant to face these stresses consists on the compartmentalization of cytoplasmic Na+ within the vacuole, by a coordinated expression of a H+ pump that uses pyrophosphate as a source of energy (known as vacuolar pyrophosphatase) and a Na+/H+ exchanger, both located on the vacuole membrane. The vacuolar pyrophosphatase has been described in various plant species, such as wheat and corn, along some woody species such as poplar and apple. In our laboratory we isolated the cDNA of the Eucalyptus globulus vacuolar pyrophosphatase (EgEPV1), establishing by real-time PCR that its transcript expression increases when Eucalyptus globulus plants are subjected to water and salt stress. An analysis of its genomic sequence allowed us to identify four introns and a promoter region of approximately 2Kb. The fusion of
the GUS reporter gene to the promoter region as well as to the first EVP1 intron allowed us to establish for the latter a possible regulatory function, in addition to identifying the promoter-specific expression in A. thaliana plants. Finally, A. thaliana transgenic plants generated by overexpressing EVP1 produced seeds that exhibited a higher germination rate in high salt conditions compared to the wild-type plants. Furthermore, adult transgenic plants had more leaves in the rosette and a higher tolerance to salt and water stress.

Overexpression of walldof transcription factor increases secondary wall deposition and alters carbon partitioning in poplar

Isabel R Gerhardt1, Silvia B Filippic, Vagner Okurad, Alexandre F Garcia3, Paulo Arruda3
1 Canavialis Alelyx, Campinas, SP, Brazil; 2 Wild-type aspen hybrid (Populus tremula x Populus alba), Campinas, SP, Brazil; 3 Canavialis Alelyx, Campinas, SP, Brazil, Present address: State University of Campinas, Campinas, SP, Brazil
E-mail: isabel.gerhardt@cnmp.embrapa.br

Background: Of the total worldwide biomass produced by land plants, 70% is represented by cell walls [1]. In angiosperm trees, the fixed carbon is accumulated mainly in the secondary walls of xylem cells, which turns xylem cell wall formation a major carbon sink in trees[2]. The understanding of mechanisms that regulate carbon flux to the synthesis of cell wall components is a fundamental goal to maximize the amount of lignocellulosic biomass.

Several families of transcription factors have been shown to be important regulators of secondary wall biosynthesis, but how plants control and direct carbon partitioning among wall components still remains unclear [3,4]. In an attempt to identify transcription factors that participate in the regulation of carbon flux into secondary wall formation, a systematic search for poplar transcription factors expressed in a wood-preferred manner was performed. We have used the collection of over 400,000 ESTs from Populus sp. available at GenBank to determine the tissue-specific pattern of genes encoding transcription factors. Among these, a DOF (DNA-binding with one finger) domain transcription factor family member (which we named WALDOF) that presents a cambium-preferred expression profile was selected for further characterization.

DOF proteins are plant-specific transcription factors suggested to participate in the regulation of biological processes such as light-regulated gene expression, photosynthetic carbon assimilation, accumulation of seed-storage proteins, germination, response to phytohormones, guard cell-specific gene expression, flavonoid metabolism, and lipid biosynthesis [5,6]. In this work, we report that overexpression of WALDOF in transgenic poplar is capable of increasing secondary wall deposition and altering carbon partitioning in poplar stems.

Methods: The collection of over 400,000 ESTs from Populus sp. available in GenBank was searched for the tissue-specific pattern of expressed genes. For this purpose, ESTs from 100 cDNA libraries were grouped into 15 representative tissues/organs including apical shoot, bark, cambial zone, catkins, cultured cells, flower buds, leaves, mixed tissues, petioles, roots, seeds, shoot meristem, shoots, vegetative buds and xylem (including xylem and wood libraries). A set of clusters generated by CAP3 was searched for those composed of at least 60% of EST reads from libraries representing poplar cambial zone and stem tissues. One cluster representing a DOF transcription factor family member with a cambium-preferred expression profile was identified. Using a CDNA synthesized from total RNA from stems of Populus deltoides plants, the full-size ORF of the WALDOF gene was cloned under the control of a 1.0 kb fragment of a Populus deltoides cinnamate 4-hydroxylase (C4H) promoter. Wild-type aspen hybrid (Populus tremula x Populus alba) was transformed with Agrobacterium tumefaciens carrying the construct.

Results and conclusions: We obtained 12 transgenic poplar lines that were transferred to soil and grown in the greenhouse. After two months, they were harvested and screened for changes in lignin deposition by phloroglucinol staining of transverse stem sections. The initial screen showed that the intensity of the staining was higher in seven of twelve lines, suggesting a stronger lignification in those plants. Based on the initial lignin screen, four of the seven transgenic lines were randomly chosen for in-depth characterization. Overexpression of WALDOF in transgenic poplar leads to a dramatic thickening of secondary wall and a reduction in the lumen area, which resulted in an increase of as much as 78% of the area occupied by wall in fiber cell cross-sections. Wall thickening at the expense of lumen area also resulted in higher wood density in transgenic lines. Moreover, WALDOF overexpressing plants presented increased cellulose content, a general reduction in hemicellulose carbohydrates, mainly mannose and arabinose, and alteration in lignin composition. Starch content in stems was also reduced in transgenic plants.

Aiming to figure out which genes could be related to the altered phenotype, we proceed with a xylem transcriptome analysis of WALDOF events using Affymetrix Genechip Poplar Genome Array. We have identified 825 genes that are differentially expressed, including a set of genes that participate in carbon and nitrogen metabolism.

The results indicate that WALDOF is involved in carbon flux regulation and carbon partitioning through cell wall formation, and can contribute for increasing biomass production.

BMC Proceedings 2011, Volume 5 Suppl 7 Page 43 of 199

The discovery leading to the realization of the importance of LBD proteins in xylem differentiation was the identification and subsequent characterization of an activation tagged mutant that shows enhanced xylem differentiation. We have found that the activation of a LBD encoding gene, PtLBD1 (Populus tremula x P. alba LBD1) with uncharacterized previously function in poplar and Arabidopsis, is primarily involved in differentiation of secondary phloem and ray cells. Transgenic gain and loss-of-function experiments demonstrated that PtLBD1 is a positive regulator of secondary phloem growth and development. Expression and localization experiments showed predominant expression in the phloem and localization of the transcript on the boundary between the differentiating phloem and the cambium. The in planta analysis identified the expression of the transcriptional regulators of meristem identity genes like ARBORKNOX1 (ARK1) and ARBORKNOX2 (ARK2) were downregulated while key regulators of phloem initiation like ALTERED PHLOEM DEVELOPMENT (APL) gene was upregulated in the activation tagged mutant line. The phenotype, localization and misexpression of ARK1, ARK2 and APL genes indicate that LBD1 is a critical component in the establishment and function of the developmental boundary between the vascular cambium and the differentiating phloem. It shows that the boundary genes like LBD have dual function to repress meristem identity but promote proliferation and differentiation. We have also found that LBD1 is downregulated by auxin and is co-expressed with strong repressors of auxin response. Because auxin concentrations peak in the cambium and LBD1 is downregulated by auxin we hypothesize that part of the molecular mechanism that establishes the boundary is through auxin-mediated repression of LBD1 in the cambium zone.

Vascular cambium of most extant plants is bifacial – producing xylem to the inside and phloem to the outside of the stem trunk. We then asked if the boundary on the xylem side of vascular cambium is organized and regulated in a similar manner. A broad preliminary survey of the LBD family in Populus identified 57 members; microarray results display that four LBD genes (PtLBD1, PtLBD4, PtLBD15, PtLBD18) show predominant expression in stems undergoing wood production with two genes expressed in the phloem (PtLBD1 and PtLBD4) and two in the xylem (PtLBD15, PtLBD18). This suggests that a similar regulatory mechanism is in operation during xylem growth and differentiation. Our studies also shed light on possible mechanisms in the evolution of woodiness and wood anatomy. The LBD proteins are present in most genomes of the sequenced species from the plant kingdom with exceptions of algae. This suggests that the LBD gene family has evolved after the colonization of land plants.

Comparative sequence analysis of putative LBD1 orthologs in several sequenced plant genomes, indicates a large and highly significant expansion of the LBD1 gene in Vitis vinifera. There were 12 putative LBD1 orthologs. Vitis is vine and has a unique wood anatomy. Most notably, the rays are highly multiseriate and secondary phloem is well-developed with multiple growth rings. The intercalation of less-lignified tissues in the xylem of vines and lianas and proportionally more developed with multiple growth rings. The intercalation of less-lignified tissues in the xylem of vines and lianas supports the plant body. One of the features of xylem cells is development of secondary wall structure between plasma membrane and (primary) cell wall. Recently, it is expected that knowledge on xylem development can be utilized for application of improvement of the plant biomass, since most portion of wood, which represents one of important sources of woody biomass, is mainly composed of two types of xylem cells, xylem vessels and fiber cells.

Previously we established the in vitro transdifferentiation system, in which Arabidopsis suspension cells could synchronously transdifferentiate into xylem vessel elements. A number of genes whose expression is elevated during the transdifferentiation processes have been isolated by using microarray analysis [1]. We revealed that one of the identified genes, which encoded a NAC domain protein, VND7 (Vascular-Related NAC Domain Protein?), plays a pivotal role in promoting the xylem vessel differentiation [1,2].

Recently, to efficiently obtain xylem vessel elements, we used a glucocorticoid-mediated post-translational induction system [3]. The transgenic Arabidopsis plants exhibited transdifferentiation of most of cells into xylem vessel elements, and the plants died. This induction system worked in poplar trees and in suspension cultures of cells from Arabidopsis and tobacco. These data demonstrate that the induction systems controlling VND7 activity can be used as powerful tools for understanding xylem cell differentiation.

**Objectives of the research:** Several studies report that VND7 regulates expression of downstream of some transcription factors, suggesting that existence of transcriptional network regulating xylem vessel differentiation. Here, in order to identify direct target genes of VND7, we performed global transcriptome analysis using Arabidopsis transgenic lines in which VND7 activity could be induced posttranslationally.

**Methods:** We generated a transgenic Arabidopsis plant expressing VND7-VP16-GR [3] driven by CaMV35S promoter. VND7-VP16-GR and VP16-GR seedlings were soaked with water containing 10 μM cycloheximide (CHX), a protein synthesis inhibitor, for 2 hours. After removal of the solution, the seedlings were re-soaked with water containing 10 μM CHX, with or without 10 μM dexamethasone (DEX), for 4 hours. Microarray analysis was performed using GeneChip ATH1 Arabidopsis genome arrays. The effector, reporter, and reference plasmids [4], were delivered into the rosette leaves of Arabidopsis by particle bombardment. After overnight incubation, luciferase activity was assayed. For electrophoretic mobility shift assay (EMSA), promoter fragments were labeled with biotin. The poly-His-tagged N-terminal region of VND7 (His-VND7 [1,16]) protein was purified from Echerichia coli.

**Results:** As shown previously, overexpression of VND7 induces expression of many genes related to the differentiation of vascular vessels [4]. Microarray analysis revealed that 300 genes are upregulated by more than two-fold in the transgenic VND7 plant. To identify direct target genes of VND7 among the upregulated genes, we used a glucocorticoid-mediated posttranslational induction system. We generated a transgenic Arabidopsis plant expressing chimera VND7-VP16-GR gene under the control of the CaMV35S promoter [3]. We subjected VND7-VP16-GR seedlings to pre-treatment with CHX, followed by treatment with or without DEX. Microarray analysis using these samples revealed that, among the 300 genes upregulated in the VND7-VP16-GR plants, 63 were also upregulated (fold change > 2; FDR < 0.1 [P < 0.026]) in the VND7-VP16-GR plants in response to DEX treatment. These genes encode a broad range of proteins such as transcription factors, IRREGULAR XYLEM proteins, and proteolytic enzymes, known to be closely associated with xylem vessel formation [5].

To define the promoter region responsible for the upregulation of gene expression by VND7, we carried out transient reporter assays using the XCP1 promoter sequence. We constructed reporter plasmids by linking various lengths of XCP1 promoter sequences to a minimal CaMV 35S promoter driving the firefly luciferase gene and the VND7 gene driven by CaMV 35S promoter was used as an effector plasmid. We concluded that the region of XCP1 promoter between residues -211 and -96 is necessary and sufficient for gene expression induced by VND7 [7].

In order to investigate the direct DNA/protein interaction between the XCP1 promoter sequence and the VND7 protein, we carried out EMSA. Two distinct regions of the XCP1 promoter were demonstrated to be responsible for VND7 binding. Furthermore, we also showed that VND7 protein binds to several promoter sequences present in candidate direct target genes [5].
Conclusions: These findings indicated that VND7 upregulates, directly and/or indirectly, many genes involved in a wide range of processes in xylem vessel differentiation. Interestingly, VND7 directly regulates lots of genes involved in programmed cell death, while most of genes controlling secondary cell wall biosynthesis could be regulated through the MYB transcription factors. Further investigation of consensus DNA binding sequences of target genes will help elucidate the regulation of gene expression in xylem vessel formation. To obtain a view of xylem vessel differentiation, we also need to reveal how the direct target genes function during xylem vessel formation.

Proteins are molecular machines that play roles in almost all biological activities through interactions with other molecules such as carbohydrates, lipids, nucleic acids and other proteins. We are mapping protein-protein interactions relevant to woody biomass production by focusing on proteins co-expressed in poplar secondary xylem. In addition to revealing novel regulatory mechanisms important to woody biomass production, mapping the poplar protein-protein interactome will provide fundamental information relevant to xylem differentiation and secondary growth. We have cloned a portion of the poplar biomass ORFeome, specifically 374 ORFs that are upregulated in xylem versus phloem, for use in protein-protein interaction research. Here we summarize the techniques we are using to discover and study protein-protein interactions and results to date.
1. Yeast two-hybrid (Y2H) binary assays: 108,205 Y2H binary assays involving over 300 biomass ORFeome members have been performed and 11 interaction pairs identified. The proportional yield from our binary screen is similar to that represented by the current preliminary binary screen data from the Arabidopsis interactome project.
2. Y2H cDNA library screening: We have used 40 bait proteins to screen our poplar xylem cDNA prey library, and a total of 60 biomass ORFeome members comprising putative regulators of lignocellulose synthesis will be screened in 2011. For the 26 ORFs that are completely through the library screen, we have identified 44 unique interacting sequences. Thus far, the half-life of interactors for proteins catalyzing metabolic reactions (such as cellulose synthase, PB138) is much lower than that for regulatory proteins (such as NIMA kinase, PB223). Results from these Y2H screens are available at our project website (http://xylome.vbi.vt.edu/index.html). Additional website information includes a project overview, project objectives, progress to date, sequences for all ORFs and primers, clone availability, and Y2H protocols.
3. Confirmation of selected protein-protein interactions identified by Y2H screens: Selected Y2H interactions are being confirmed by independent methods including bimolecular fluorescence complementation (BiFC) and co-immunoprecipitation/affinity purification using plant transient or stable expression systems. We have developed improved vectors and protocols for reducing background fluorescence during BiFC experiments.
4. Functional analysis: We are characterizing the functions of selected interacting pairs in both poplar and Arabidopsis by ectopically expressing or suppressing genes singly and in combination. For ectopic and/or over-expression experiments we are using 3SS, SUC2 (phloem specific) and XCP2 (xylem specific) promoters. Co-expression of 3SS:PB15 and 3SS:PB129 in Arabidopsis resulted in expanded interfascicular regions containing enlarged fibers compared to fibers in wild-type plant interfascicular regions of the inflorescence stem. Importantly, this phenotype was not observed in transgenics overexpressing just one of these genes, showing the potential of novel interactome data to be translated into alteration of wood phenotypes. Arabidopsis mutants carrying T-DNA insertions within Arabidopsis orthologs of PB15 and PB129 are also being evaluated, and Populus RNA interference (RNAi) lines have been generated to study the effects of silencing PB15 and/or PB129 and their paralogs.
5. Transgenic poplar field trial: We prepared transgenic poplar overexpressing 11 biomass genes as tandem affinity purification-(TAPA)-tagged fusions and established these in a replicated field trial, which will be evaluated for overexpression phenotypes and serve as a source of xylem for identification of co-purified proteins.

O39 Identification of laccases involved in lignin polymerization and strategies to deregulate their expression in order to modify lignin content in Arabidopsis and poplar

Lignins have a major impact on the agro-industrial uses of plants. Until now, most of the strategies considered for lignin reduction have targeted the monolignol pathway since the genes involved in these metabolic steps have been identified in many plants. Less is known about the other steps and in particular on lignin polymerization in the cell wall. While it is established that peroxidases are involved in the polymerization of lignin precursors, it is not yet clear whether laccases (EC 1.10.3.2) participate in constitutive lignification.
In order to address this issue, laccase genes (AtlAC4 and AtlAC17) that are highly expressed in Arabidopsis stems were studied. AtlAC17 was specifically expressed in the interfascicular fibers while AtlAC4 was expressed in vascular bundles and interfascicular fibers. Arabidopsis T-DNA insertion mutants were selected and characterized. Two double mutants were obtained by crossing the AtlAC17 (lac17) mutant with two AtlAC4 mutants (lac4-1 and lac4-2). The single and double mutants displayed normal growth, except the lac4-2 lac17 mutant that sometimes had a semi-dwarf phenotype and collapsed vessels. While the single mutants had moderately reduced lignin levels, the stems of lac4-1 lac17 and lac4-2 lac17 had lignin content reduced by 20% and 40%, respectively. This lower lignin level improved their saccharification yield. Thioacidolysis revealed that disrupting ATlAC17 mainly affected the deposition of G lignin units in the interfascicular fibers and that complementation of lac17 with AtlAC17 restored the normal lignin profile. This study provides evidence that both AtlAC4 and AtlAC17 contribute to the constitutive lignification of Arabidopsis stems and that AtlAC17 is involved in the deposition of G lignin units in fibers, suggesting a role in early lignification (Berthet et al, in press).

The double mutants cannot be obtained for species that are propagated vegetatively such as poplar. In order to produce plants with lower laccase activity and reduced lignin content, we therefore used a miRNA strategy. The overexpression of two miRNA (miR597 and miR408) targeting several laccase genes was tested in different plants including Arabidopsis and poplar. These miRNAs were expressed constitutively under the control of
the CaMV 35S promoter or of lignin-specific promoters such as CAD and C4L in transgenic Arabidopsis and poplar. Results obtained using of this miRNA strategy in Arabidopsis and preliminary results for poplar will be presented.

An AC-type element mediates transactivation of secondary cell wall carbohydrate-active enzymes by PttMYB021, the Populus MYB46 orthologue

Background: The transcription factor MYB46, together with its redundant paralog MYB83, regulates expression of secondary cell wall biosynthesis genes in Arabidopsis [reviewed in 1]. We isolated the Populus MYB46 ortholog, PtxtMYB021 from hybrid aspen (Populus tremula x tremuloides) [2]. Transiently expressed MYB021 transactivated gene promoters of Populus xylan-active enzymes GT43A, GT43B and Xyn10A. Analysis of conserved motifs within these promoters identified the sequence CCACCAAC, which is similar to the AC elements mediating transactivation by MYB transcription factors during lignin biosynthesis, and we showed that this motif is enriched in xylem-specific carbohydrate active enzyme (CAZyme) promoters.

Methods: To establish whether the AC-type motif in CAZyme promoters is important for their function, we analyzed loss-of-function and gain-of-function GUS reporter constructs of the GT43A promoter in a transient transcription assay, by co-infiltration with a 35S:MYB021 effector in Nicotiana benthamiana leaves.

Results and discussion: We show that mutation of the AC-type element in the GT43A promoter abolishes transactivation by MYB021, whereas an AC multimer confers MYB021 transactivation to a minimal 35S promoter. Others have shown that the recombinant Eucalyptus grandii MYB46/MYB83 ortholog, EgMYB2, directly binds the AC-motif variant CCACCTACC found in the EgCCR gene promoter [3], suggesting that MYB021 directly binds the AC-type motif. We propose that, in angiosperms, the AC-type regulatory element mediates MYB46’s transactivation of its target genes. Further, MYB46 activates lignocellulose synthesis in a feed-forward loop with downstream MYBs, involving both direct activation of downstream MYBs and joint regulation of downstream secondary cell wall synthesis targets (Fig. 1). Recent results show direct activation of downstream lignocellulose synthesis targets by higher hierarchy NAC domain regulators [4,5]. Interestingly, the downstream MYB regulators of lignin biosynthesis MYB58 and MYB63 bind the AC element but reportedly do not regulate CAZyme-mediated secondary cell wall polysaccharide biosynthesis [6]. Other downstream MYBs that bind variants of the AC element are the EAR domain lignin repressors, such as EgMYB1 and ZmMYB31 (Table 1). Then, binding of the distinct lignocellulose synthesis MYB transcription factors to particular AC-element variants may be mediated by motif sequence, motif context and/or interactions with cofactors. Also, some AC element variants overlap extensively with each other and with the AC-type element defined.

Figure 1(abstract O40) Regulatory networks in lignocellulose synthesis in angiosperms, shown using Arabidopsis gene nomenclature, involve feed-forward loop circuits. Dashed arrows highlight direct target gene activation by higher hierarchy regulators. White boxes at the bottom indicate target gene programs. For simplicity, some regulators, including ASL19, MYB103 and KNA77, are omitted. Adapted from [1] and references therein.
by us (Table 1), so it remains to be established whether they are all representatives of one identical core sequence motif, as previously proposed [7]. Establishing the exact sequence requirements for AC-element recognition by distinct MYBs will facilitate elucidation of lignocellulose-related regulatory networks in different species, through bioinformatic analysis [8].

Conclusions: The AC regulatory element, here preliminarily redefined as the sequence CCACCAAC, is a true "lignocellulose synthesis response element", mediating MYB46-dependent transactivation of the whole secondary cell wall gene program. This knowledge will enable inference of MYB46-centered regulatory networks in different species, through bioinformatic analysis.

BMC Proceedings 2011, 5(Suppl 7):O41

Detailed knowledge of the tissue specificity of gene expression is of central importance not only for our understanding of developmental processes during wood formation, but also is a prerequisite for the deliberate manipulation of xylogenesis candidate genes. Today, much of our knowledge about specific gene expression is based on annual model plants in part because perennial tree systems are often seen as too cumbersome for detailed promoter studies. Here we address this issue in a novel way with the investigation of a number of well characterised cellulose synthase (CesA) genes in the stems of perennial tree species using the in vivo Induced Somatic Sector Analysis (ISSA) system. Three primary and four secondary cell wall associated CesA gene promoters from Eucalyptus grandis and Arabidopsis thaliana were previously isolated and cloned in front of the GUS reporter gene then, using Agrobacterium-mediated transformation, transformed into cambial initials in stems of eucalypt and poplar plants. A CAMV35S promoter:GUS vector was also used as a control. After a period of growth, stems were harvested and GUS-staining patterns were analysed and interpreted. Results from this work show that in eucalypts the staining patterns are consistent with observations in other species whereas in poplar conflicting results were observed. These findings and the general utility of ISSA for these studies are discussed.

Variation of telomeric repeats in Scots pine (Pinus sylvestris) – is there a connection to ageing and loss of regeneration ability?

Tuija Aroen

Finnish Forest Research Institute, Punkaharju Unit, FI-58450 Punkaharju, Finland

E-mail: tuija.aroen@metla.fi

BMC Proceedings 2011, 5(Suppl 7):O42

The shortening of telomeres, the specific expression of repeated DNA sequence at the end of the eukaryotic chromosomes, has been connected with ageing and loss of cell replication or regeneration capacity. There is, however, only limited information available on telomeres of long-living trees. Physiological ageing, on the other hand, represents a serious
problem for vegetative propagation of conifers, while in deciduous tree species ageing has no such a strict influence on regeneration ability. The aim of this study was, for the first time, to determine the variation in telomeric repeats in an economically important Nordic conifer, Scots pine (Pinus sylvestris L.), and to study potential connections to tree ageing. Scots pine individuals ranging from immature embryos to 200-year-old trees were examined. In 1- and 5-year-old seedlings and 50-, 100- and 200-year old trees, cambium, bud and needle samples were collected from different positions within a tree. The length of telomeric repeats in the extracted total genomic DNA was then determined by Southern hybridisation. In addition, telomerase enzyme activity was measured from the protein extracts prepared from the same tissues using TRAP (Telomeric Repeat Amplification Protocol).

In Scots pine samples, the size of telomeric repeats detected was variable, ranging from 0.9 kb up to 26 kb. Based on exonuclease treatment, high molecular weight repeats seem to be genuine telomeres at the ends of the chromosomes, while the low molecular weight signals probably originate at interstitial or centromeric positions. The Southern hybridisation was thus adjusted to show only high-molecular weight signals, and analyses were performed based on them. A decline in the average length of the telomeric repeats was observed with increasing level of tissue differentiation: immature and germinating embryos, had the longest repeats, followed by cambium, elongation buds with tiny meristems and, finally, full-sized needles without meristems having the shortest repeats. When embryo samples were excluded from the data, the age of the tree had no significant effect on the length of telomeric repeats, although there was a tendency for telomere shortening with increasing age. In cambium samples, also the position of the tissue within tree (stem base versus top) affected the length of telomeric repeats. The telomeres shortening towards top of tree. The telomeric repeats also varied remarkably between tree individuals. Potential connections to regeneration ability are discussed.

Methods: Agrobacterium tumefaciens strain EHA105 was used for the co-transformation. Vectors containing OxO and GFP were introduced to EHA105 separately via electroporation so each Agrobacterium had only one vector. Transformed EHA105 were grown separately under the selection of kanamycin and rifampicin until an O.D. of 0.8-1.2 was reached. Agrobacterium with optimum O.D. were harvested and re-suspended in vir induction medium containing acetosyringone. To approximately equalize the concentration of bacteria samples with different vectors, the amount of vir induction medium added was calculated by multiplying the O.D. value with 50ml. Bacteria samples were incubated in vir induction medium for three to four hours under room temperature with slow agitation. After vir induction, bacteria samples containing different vectors were mixed together in two different volume ratios: 2 (OxO):1 (GFP) and 4 (OxO):1 (GFP). The mixture was then added to embryo clusters to bring a total volume of 6ml followed by cocultivation on a turning machine for an hour at room temperature. After the co-cultivation, embryo clusters were taken out to put in desiccation plates (plates with 200ul ddH2O saturated filter paper) and kept in dark for two days under room temperature. After desiccation, embryos were transferred to Agro-kill medium containing carbenicillin and cefotaxime and kept in dark under room temperature. After a week, embryos were transferred to selection medium containing carbenicillin, cefotaxime, and appropriate selection agents (herbicide PPT and paromomycin in our case). Embryos were transferred to fresh selection medium every two weeks and were examined for GFP expression under a UV microscope (Figure 1).

Results and discussion: Thirteen experiments with a total of 208 embryo clusters were done using the 2 (OxO):1 (GFP) ratio resulting in 50 GFP positive events. 10 out of the 50 events were also OxO positive, giving a co-transformation efficiency of 20%, or 4.8% per embryo cluster. Three experiments with a total of 150 embryo clusters were done using the 4 (OxO):1 (GFP) ratio resulting in 45 GFP positive events. 18 out of the 45 events were also OxO positive, giving a co-transformation efficiency of 40%, or 12% per embryo cluster. Doubling the ratio of vector containing gene of interest to vector containing the selectable marker from 2:1 to 4:1 gave a 2.5-fold increase in co-transformation efficiency. All of the 28 events went through the regeneration process together with 6 GFP-only events. 4 out of the 10 events produced by 2:1 ratio regenerated into whole plants. 17 out of the 18 events produced by 4:1 ratio regenerated into whole plants. All 6 GFP-only events regenerated into whole plants. These regenerated American chestnut plants seem to exhibit normal morphology. A gradient of OxO expression levels were found with the highest being more than 200 fold higher than the lowest expressed event.
Copy numbers of the transgene axo were also tested via RT-PCR showing most events with 2 copies, few with single copy, and a couple with higher copy numbers. The difference in regeneration ability and expression levels among these events was likely a result of position effect, which the expression of foreign gene is affected by the insertion site and nearby regulatory factors in the genome.

**Conclusions:** The efficiency of Agrobacterium-mediated co- transformation of American chestnut somatic embryos improved significantly when increasing the ratio of vector containing the gene of interest to vector containing the selectable marker in the co-cultivation mixture. Other factors of co-transformation including Agrobacterium strain, co-cultivation time, and desiccation time, etc. can also be investigated to improve the overall efficiency of this process. Co-transformation proved to be an effective way to introduce foreign genes into American chestnut to test their effectiveness on chestnut blight resistance. Having GFP on a separate plasmid provided a useful tool for removing of the marker gene in future. However, further tests need to be done to determine whether the GFP gene is linked to axo in the genome.

E-mail: devegabartol@itqub.unl.pt

**BMC Proceedings 2011, 5(Suppl 7):**044

Clonal propagation by somatic embryogenesis (SE) has a great application potential in conifers, but its efficiency still needs further improvement. Quantitative PCR (qPCR) is widely used for gene expression analysis during SE as part of studies to characterize gene function. In qPCR, data is normalized against a reference gene with a uniform expression during the tested conditions. Studies have shown that no single housekeeping gene is universal for all experiments, so a systematic characterization of several endogenous genes for concrete conditions is fundamental for biological accuracy.

We evaluated 10 genes present in *Pinus pinaster* selected among those commonly used as endogenous reference in conifers (actin, α-tubulin, elongation factor 1α, adenine kinase and ubiquitin), previously tested in model plants (Histone 3, SAND protein and clathrin adaptor complex -CAC- subunit), and with a lower variation of expression in five RNA samples at different embryogenesis stages according to microarray hybridization results (homologous to a heat shock protein -HEATSK- and to an ether reductase –REDUC-) (Simões et al., unpublished results). Stability of the expression in three developmental stages (embryogenic tissue, mature embryos and germinated embryos) was evaluated with two different algorithms (implemented by programs geNorm and Normfinder), both in *Pinus pinaster* and *Picea abies*, so results could be expanded to other conifers. Previously, efficiency was calculated with programs Linreg and qPCR miner and the distribution of Cts by statistical boxplot analysis, for each amplicon.

Results evidenced that the geometric averaging of two-to-four of these genes is accurate enough. Using genes elongation factor 1α, SAND and α-tubulin as reference is the better generic combination, and so probably the preferable option to consider in other conifers. Among them, SAND and α-tubulin had a reduced range of Cts, while it was higher in elongation factor 1α, especially in *Pinus pinaster*. Some discrepancies were detected in the ranking base for stability for the other genes, so this generic combination can be improved in certain stages or species, like adenine kinase in *Pinus pinaster* or CAC when analysing embryogenic tissue in proliferation. Adenosine kinase and ubiquitin are also acceptable options, as they showed small ranges of Cts and medium stability values in the three stages in both species. By contrast, several genes showed a higher variation in our experiments, as both selected from the microarray analysis (REDUC and HEATSK), and one commonly used reference gene (actin), which evidence the importance of these kind of studies.

**BMC Proceedings 2011, 5(Suppl 7):**045

**Background:** The wide adaptability, fast growth rate, good form, excellent wood and fiber properties make *Eucalyptus* the most widely planted genus of plantation forest trees. With the availability of *Eucalyptus* genome sequence information, assignment of function to genes contributing to desired traits require functional validation via overexpression or silencing in the context of the plant environment. However, plant regeneration from transformed tissues has been the most time consuming and rate-limiting step for rapid gene function analysis in tree species. The composite plants with transgenic hairy roots derived via *Agrobacterium rhizogenes* mediated transformation are therefore increasingly being used in species with such limitations to study root development and root-biotic interactions. In this paper we describe a protocol developed for generation of composite plants using *A. rhizogenes* mediated transformation of *Eucalyptus camaldulensis*.

**Methods:** Transformation experiments were carried out using an agropine mannopine-type strain A4RS, harbouring a green fluorescent protein (sGFP) based binary vector pHKN29, constructed from pCAMBIA 1300 by replacing hygromycin phosphotransferase (hpt) with the sGFP(SEST) [2]. Infection was carried out using a sterile needle swabbed with *A. rhizogenes* grown for 48 hours in YEB plates containing 100 μM Acetosyringone. The infected plants of *E. camaldulensis* were then placed under dim light on modified MS [3] medium comprising half strength MS macro elements, full strength MS minor elements and organic supplements. The petioles were placed slantly with the plants in an upside-down position. Following cocultivation, the cultures were transferred to fresh medium with plants in an upright position. Hairy roots were made bacteria-free by making transfers every 15 days to fresh medium containing 500mg/l cefotaxime. The hairy roots generated were examined under a stereo fluorescence microscope (Nikon, Japan) for visualization of GFP following excitation by blue light (Excitation filter 495nm, Barrier filter 520nm). The nontransformed roots were removed using sterile blades. The composite plants were placed in test tubes, and different media including full MS, modified MS, Knop’s, B5 and Hoagland’s solutions were evaluated for growth under hydroponic conditions. The composite plants were shifted to the transgenic greenhouse, where in the cotton plugs were loosened gradually and finally removed after a period of 2 weeks. The plants were then placed so that roots were immersed in the liquid media and shoots were above the test tube rim covered with aluminium foil. Few of these plants were subjected to stepwise increasing concentration of 50mM NaCl to determine their tolerance to salt stress.

**Results and discussion:** Inoculation with A4RS resulted in roots, arising mainly from the injured surface of the explants. Root initiation occurred within first 7 days after inoculation of explants with *A. rhizogenes*. The roots reached a length of 8-10cm in 45 days. The results were similar to the report of MacRae and Van Staden (1993), where in genetic transformation using the *A. rhizogenes* strain LBA 9402 was assessed by the detection of opines in the root generated from in vitro propagated seedling explants of *E. grandis, E. dunnii* and *E. nitens*. In our study, the bright green fluorescence due to co- transformation of the pHKN29 vector harbouring the sGFP(SEST) was used for screening of transgenic roots (Figure 1). No fluorescence was observed in untransformed control roots of *Eucalyptus*. 

**Effect of explant type:** Seedlings showed root induction in 68% of the explants at an average of 1.06 roots per plant of which 36% were transformed with the pHKN29 as confirmed by the GFP expression. The in vitro propagated clonal plantlets showed root induction in 37.5% of the explants at an average of 0.45 roots per plant of which 4.1% showed GFP expression.

**Effect of cocultivation conditions:** In a separate experiment, out of the four different basal media used for cocultivation, modified MS media gave the highest average number of hairy roots at 1.3 per plant, when
compared to 0.8, 0.7 and 0.6 in case of 0.1 MS, Knop’s and Hoagland’s media (Figure 2).
Different supplements like phosphate buffer and calcium chloride were included in the cocultivation media to evaluate their influence on hairy root induction. Addition of calcium chloride to the cocultivation media reduced the average number of hairy roots induced per plant by 30%. Similarly, phosphate buffer also did not significantly influence the hairy root generation. However, the inclusion of 100 μM acetosyringone in the cocultivation medium increased the average number of hairy roots to 1.6 per plant as compared to 1.3 for media without acetosyringone (Figure 2). Acetosyringone has been known to enhance transformation efficiency through activation of vir genes in Agrobacterium.

Preliminary experiments indicated that, cotransformation efficiency was higher when cocultivation was carried out at 16.5°C for 14 days when compared to 22°C for 7 days.

**Effect of different liquid media on hardening of composite plants:**
Different liquid media were evaluated for hardening of composite plantlets. Hoagland’s solution showed the highest survival (73.3%) when compared to MS (20%), modified MS (16%), BS (0%) and Knop’s (3.3%).
To determine the tolerance of these composite plants under salt stress, they were subjected to weekly increase in the concentration of NaCl by 50 mM. Fifty percent of the Eucalyptus composite plants were able to tolerate up to 300 mM NaCl stress.

Conclusion: A composite plant strategy was developed utilising GFP based screening of transgenic hairy roots. Different parameters were evaluated to increase transformation efficiency using A. rhizogenes. Our studies showed that, modified MS media containing 100 μM Acetosyringone was optimum for enhancing the cotransformation efficiency. Hoagland’s solution was identified as an appropriate media for hardening of Eucalyptus composite plants under transgenic green house conditions. Roots being the major point of entry for the plants, the composite plant strategy will provide a rapid tool for the functional analysis of the genes vital for ion transport and root development. The composite plant strategy will be used to validate the function of ECHKT1/EHKT1, the homologue of which have been reported to contribute to Na uptake and xylem unloading of Na in model plant and crop species.

seed’s maternally derived haploid tissue, the megagametophyte. Analyzing a set of sibling megagametophytes allows us to first, measure separately the expression each of the two alleles in the maternal genome in the absence of dominance and second, identify genes whose expression levels are co-segregating. In addition, the megagametophyte allows us to categorize the underlying genetic variants into local or distant with a simple co-segregation assay.

Methods: We set out to characterize segregating variation in gene expression in white spruce (Picea glauca [Moench] Voss). We analyzed the transcriptomes of germinating sibling megagametophytes from two controlled-crossed families (C9412156: male 2388 x female 77111 & C9612856: male 80109 x female 80112) with a custom microarray comprised of 32,000 spotted oligonucleotides, which represent over 25,000 unique white spruce genes. Each megagametophyte was split into two halves to provide technical replicates that were analyzed separately. A separate comparison of microarray results and RNA-Seq data has been carried out to validate the quality of the microarray.

The single-color microarray data was background-corrected and quantile-normalized with the R package Limma [4]. We used the R package Mclust [5] to test for unimodal vs. bimodal expression distributions of each gene across sibling megagametophytes. Genes that exhibited at least two expression alleles, which segregated within the 95% IC of their expected proportions were selected. The segregation had to be repeatable with a replicate sample set to be considered valid.

Results and discussion: Analysis of two families of sibling megagametophytes (n=18) identified close to a thousand genes with segregating gene expression patterns in both of the two families. Approximately 10% of these genes were shared. Zero replicates are expected to have the same clustering pattern by chance alone (binomial p=0.810-6 n=18). The number of variable genes is comparable to that found by 50 nearly isogenic Drosophila lines [6].

We have discovered a large number of genes with gene expression patterns segregating in a Mendelian way in white spruce. We are presently analyzing the relationships between gene function and paralog number with the variation in its expression in order to determine whether heritable variation in gene expression is associated with same genetic attributes in white spruce as what has been reported in model organisms. We have also begun investigating the contribution of local vs. distant effects on the expression alleles identified in the megagametophytes, and their nature, by studying the co-segregation of gene expression, SNPs and copy number variations (CNVs). Preliminary comparative genomic hybridization data suggests a significant portion of genes which show segregating gene expression alleles also exhibit CNVs. In follow-up experiments, we will address the amount of dominance between the gene expression alleles by comparing gene expression in megagametophytes versus self-fertilized embryos.

Acknowledgments: The seed material was provided by J. Beaulieu (Canadian wood fibre centre).

Targeted sequencing in the loblolly pine (Pinus taeda) megagemome by exome capture

Leandro Neves1, John Davis2, Brad Barbazuk3, Matias Kirst4
1Plant Molecular and Cellular Biology Program, University of Florida, Gainesville, FL, USA; 2Plant Molecular and Cellular Biology Program and School of Forest Resources and Conservation, University of Florida, Gainesville, FL, USA; 3Plant Molecular and Cellular Biology Program and Department of Biology, University of Florida, Gainesville, FL, USA; 4E-mail: gomide@ufl.edu

Background: An essential use of genomics is in the discovery of genes controlling complex, quantitative traits. In forestry, attempts to identify genes that regulate quantitative variation are still limited to a few Association Studies (AS) focused largely on candidate genes [1]. In most studies, few markers have been identified in association with quantitative traits.

Recent advances in DNA sequencing create the potential for high-throughput SNP genotyping at low cost, by re-sequencing genomes of interest [2]. For the particular case of conifers, two obstacles remain: (i) the lack of a reference genome to align the DNA sequences and identify SNPs, and (ii) the size and complexity of the genome that hinders the de novo assembly of reads. Whereas whole-genome sequencing of a large number of conifer genotypes is still unfeasible, concentrating the sequencing on gene-rich regions is an alternative to generate markers that are more likely to capture variation associated to complex traits. Here we report our approaches to develop methods of genotyping based on whole-exome capture using in-solution target enrichment (Agilent’s SureSelect) followed by high-throughput sequencing (Illumina’s GAIIx).

Methods: Probes for target enrichment: To capture a defined genomic portion of the Pinus taeda genome we designed 54,773, unique, 120-mer RNA probes that tilled across a collection of 14,729 EST assemblies (unigenes). For 3,615 genes we could predict gene models and avoid probes on known exon-intron junctions.

Genetic material, library preparation and sequencing: A total of 72 seeds collected from a female tree (10-5 genitor) were used for library preparation. Haploid megagametophyte tissue was dissected and DNA was extracted using standard protocols. Libraries were prepared as recommended by Illumina, with some custom modification of concentration, adapter sequence and fragment size selection. Custom barcoded adapters were used to pool up to eight genotypes in a single hybridization, which followed Agilent’s SureSelect protocol. Captured-libraries were sequenced using GAIIx with 115nt single-end run.

Results and discussion: Preliminary validation: To test the potential of target enrichment in pine we prepared sequencing libraries from three different genetic complexities from single genotypes/haplotypes: haploid cDNA from megagametophyte (n=12), haploid DNA from megagametophyte (n=12) and diploid DNA extracted from needles (2n=24). After hybridization of these libraries to SureSelect probes, we cloned each captured library into vectors and sequenced 96 fragments using Sanger sequencing. After reads were aligned to the reference sequences used for probe design (BLAST e-value=1x10^-16), 70, 84 and 80% of the quality-filtered reads from haploid cDNA, haploid DNA and diploid DNA aligned uniquely to a unigene, respectively. Therefore, sequence capture is highly specific, even when the complexity of the material increases.

Pipeline development for mapping population: We modified the sequence capture protocol to increase throughput by constructing libraries from haploid DNA of 72 megagametophytes in 96-well plates. An average of 25.9 million single-end reads were obtained from flow-cell channel containing 8 barcoded megagametophytes, for a total of 56 megagametophytes sampled across 7 channels lanes. The remaining two pools (16 individuals) have not been sequenced. Despite multiplexing a large number of megagametophytes, we detected low variation in read numbers between haplotypes within a multiplex reaction (Figure 1). Due to the lack of a reference genome, bioinformatics experiments were designed to test whether the best approach to identify polymorphisms would result from aligning the sequences directly to the unigene sequence using Mosaik (http://bioinformatics.bc.edu/marthlab/Mosaik), or by alignment of reads to a new reference sequence defined by de novo assembly of the captured reads with the ABYSS (3)short read sequence assembler.

The analysis using Mosaik compared different levels of polymorphism between reads and the unigene sequences resulting from alignments over a range of mismatch tolerances (from 1% to 50%). Figure 2A shows that the number of reads that aligned to a single region of the reference (i.e. uniquely aligned) increases linearly until 10% of mismatches in the alignment are accepted, and stabilizes after that. Interestingly, the
percentage of reads non-uniquely aligned remains lower than 2%, regardless of the mismatch rate. Next we tested if accepting higher mismatch rates adds more reads to the same genes, or if genes previously not captured are now represented. Again, at a 10% mismatch rate (Figure 2B) the total number of genes with at least one read aligned reaches its maximum, with 22% of the reads aligning to more than 10,000 genes.

Analyzing the data using a de novo assembly approach does not appear to be more suitable. ABySS assemblies were performed utilizing a range of k-mer values (50 to 95, increments=5) and the contigs formed were analyzed. As expected, the number of contigs drops considerably as a function of the k-mer size (Figure 2C). To evaluate the quality of contigs generated at each k-mer, we compared them to the unigene sequences (BLAST identity≥85%) and counted the number of genes represented by at least one contig. This number decreased as a function of the k-mer size (Figure 2D); and, within the same genotype the sequence assemblies generated using a high k-mer were already present in the assembly using a lower k-mer. However, when comparing two genotypes assembled with the same k-mer value about 30% of the genes are unique to each genotype. This suggests that additional sequencing is necessary for an adequate analysis of the efficiency of sequence capture.

We are currently sequencing the same libraries from both ends (i.e. paired-end sequencing) to increase coverage and depth. This sequencing data is expected to identify additional SNPs markers for segregation analysis, and to help define the sequencing requirements to confidentially perform target-enrichment resequencing and genotyping in complex genomes.

Background: The fast growth and good wood properties of Eucalyptus tree species and hybrids make them excellent renewable sources of fiber for pulp and paper production, and woody biomass for bioenergy production. Our research is aimed at understanding the genetic regulation of wood formation in eucalypts, with a focus on transcriptomics, regulatory sequences and gene families involved in secondary cell wall biosynthesis.

Methods: We have performed deep mRNA sequencing (using Illumina RNA-Seq technology) of several primary and secondary tissues of three Eucalyptus grandis trees with the aim to investigate the transcriptional control of cellulose biosynthesis and wood formation. The transcriptome datasets range from near mature xylegenic tissues to immature shoot tips, and consist on average 35 million paired-end 80bp short reads. The Illumina short reads were mapped to the latest Eucalyptus grandis genome sequence (DOE-JGI v. 1.0, http://www.phytozome.net), and the set of predicted gene models provided by the Joint Genome Institute (JGI). We calculated tissue specific gene expression (FPKM) profiles for each of the ~44 000 predicted genes across the sequenced transcriptome datasets. The results were stored in a relational database for further analysis and analysis of co-expression patterns in the expression profiles. We ultimately aim to identify genes that are differentially expressed and co-regulated during different stages of wood formation.

Results: We describe the initial development of an Integrative Eucalyptus Genome Explorer (EucGenIE), modeled after the poplar resource, PopGenIE (http://www.popgenie.org, Sjödin et al., 2009). EucGenIE relies on a relational database system that allows for the efficient storage and retrieval of gene models and expression values from the database, which is then presented to the user in novel and intuitive ways. The web-based front-end makes use of tools available in the Generic Model Organism Database (GMO, http://gmod.org) toolkit such as the query interface as well as result visualization. Links to the Phytozome GBrowse instance provides genomic context to the expressed gene sets. Custom queries allows the user to find genes with similar gene expression profiles across the various datasets, as well as perform bulk searches on sequence features annotated on the gene set. EucGenIE also provides access to common analyses tools, such as homology searching and online clustering. The first version of the EucGenIE database and online portal is available at http://eucgenie.bi.up.ac.za with restricted access.

Reference
Repeats) also were considered as a tool in selecting germplasm for breeding purposes. In vitro germplasm collection of 1300 accessions from 12 countries was established. This collection will serve different purposes: a) conserve valuable genetic resources; b) survey genetic variation; and c) serve as starting material for genetic improvement with different breeding goals. Ecotilling was applied to 12 different genes of interest related to stress tolerance, toxin and oil metabolism. 50 ISSR primers were used to assess the genetic diversity of Jatropha curcas and related species. Four different pooling strategies were used to identify homozygous and heterozygous SNP variations. In fact, variation was analyzed both within a single tree (heterozygous) as well as between individual trees and a reference samples. Due to the reported low variations between Jatropha accessions [8,9], and large size of our collection, the 8 x 8 pooling strategy was chosen to estimate the level of variations among 12 selected genes.

Results and conclusions: To elucidate genetic relationship among Jatropha accessions from different regions and related species, a dendrogram was produced using NJ analysis of Nei’s genetic distance for 5 ISSR markers. The dendrogram is divided into two groups, one containing all Jatropha accessions and the other containing the related species. The main Jatropha curcas cluster is divided into two subclusters, one containing samples from Kenya and the other containing the remaining Jatropha accessions. The data showed clear variations not only among individuals but also between different regions.

Ecotilling was found to be more efficient for large-scale studies of genetic variation in Jatropha, compared to RAPD, SSR and AFLP. Ecotilling is a low cost, high-throughput reverse genetic method for haplotyping and SNPs discovery. The level of differentiation observed was based on the geographic distribution pattern, i.e. it was higher in the centre of the region. ISSR analysis yielded highly reproducible patterns with 5/50 primers.

BMC Proceedings 2011, 5(Suppl 7):OS1

Background: The sequence of the whole genome of black cottonwood (Populus trichocarpa) was made available in public domain (http://www.phytozome.net/poplar ) few years ago. Sequencing and annotation of the genome of an organism yields a tremendous amount of data and information on putative genes, however, often without any idea on their functions. To understand how a cell works one needs to know the function of almost every gene in its genome. Once the whole-genome information is available for an organism, the challenge turns from unravelling the parts to understanding their function as well as to improving genome structure. In the short term, the first goal is to assign some element of function to each of the genes in an organism also referred to as ‘functional genomics’, and to do this with high-throughput, systematic approaches.

Material and methods: Gene technology is a very powerful tool in forest tree breeding programs as well as for functional genomics in order to unraveling gene functions. Various reverse and forward genetics strategies are ongoing to determine the functions of genes and regulatory sequences. A significant progress has been made by using T-DNA as a vehicle to induce either "Knock-out" or "Knock-in" ("gain-of-function" or Activation tagging) in different plant species including poplar [1].

The application of a transposon-based activation tagging system for poplar has been proposed early by [2]. It could be shown that the maize transposable element Ac is functional in the Populus genome [3], and re-integrations occur in high frequencies in or near coding regions [4]. Further, the majority of the re-integrations were found scattered over many unlinked sites on other scaffolds than the one carrying the original insertion locus, confirming that Ac does in fact cross chromosome boundaries in poplar [5].

Results: In this paper, we describe for the first time the development of an efficient activation tagging system for poplar based on a non-autonomous “Activation Tagging Ds” (ATDs) system [6] in combination with a heat-inducible Ac-transposase. First, seven independent transgenic lines were obtained transformed with H5P:transposase construct. From these, two transgenic lines were selected for super-transformation with the ATDs-rolC construct based on the construct by [6]. The ATDs original integration could be determined from 18 double transgenic lines. Induction of the transposase gene and mobility of the ATDs element could be confirmed. Four activation-tagged populations comprising in total 12,083 individuals from 22 different ATDs transgenic lines have been passed, and phenotypes on Ac tagged lines, with several independent variants the new ATDs genomic position was successfully determined. Sequences obtained were blasted against the publicly available genome sequence of P. trichocarpa v2.0 (Phytozome v5.0; http://www.phytozome.net/poplar). E-values of hits ranged from -35 down to zero. Annotation of the sequences obtained against P. trichocarpa revealed for 13 variants possible transcripts. For five putative proteins either no functional annotation or unknown function was found.

In a second approach, 300 randomly selected individuals revealing no obvious phenotype from the forth activation-tagged population were screened for ATDs excision. In approximately one third of the investigated individuals transposition of ATDs was confirmed, and analyses of the new genomic positions of ATDs reveal a very high percentage of tagged genes.

Conclusions: Tagging approaches based on T-DNA insertion are effective only for plant species (like Arabidopsis and poplar), whose are easily transformable in combination with high frequencies of tagged lines obtained. An advantage of T-DNA based activation tagging could be that even T-DNA insertion sites are not randomly distributed in the genome but do show some insertion site preferences to the 5'UTR of a gene coding region. For transposable elements, however, new insertion sites were found scattered throughout the genome at many unlinked sites. But similar to [5] results for poplar, also other reports describe preferential transposon insertion around transposon donor sites [7].

The fact that a transposon is able to jump to other chromosomes, thus passing chromosomal boundaries, leads to the convenient situation that only a few primary transposon transgenic lines are sufficient for the establishment of large transposon tagging populations in order to tag at least theoretically every gene in a tree genome. This is obviously difficult for T-DNA tagging as plant transformation is time consuming and, therefore, the genome can’t easily be saturated with T-DNA tags. To that together, so far to date many for both T-DNA and transposon activation tagging is first to phenotype an existing tagging population and then to determine the new genomic insertion locus of the tag. A novel strategy of activation tagging can be suggested based on the described power of the ATDs transposon approach and the simplicity to induce ATDs transposition in vitro. The ATDs-based strategy allows first the production of a very high number of independent transposon-transposon plants whose can be screened for new ATDs flanking genomic loci.

BMC Proceedings 2011, 5(Suppl 7):OS1
The economic importance of some *Eucalyptus* species, including interspecific hybrids, has been extended from the traditional interest of pulp and paper production to the emergent areas of bio-fuels and bio-materials. New genomic resources and high throughput technologies have provided the *Eucalyptus* research international community with the opportunities to identify genomic regions of interest in order to comprehensively dissect, catalogue and characterize genes involved in the determination of wood formation and quality. Similar strategies can be now applied to identify key regulator genes and better understand the cellular mechanisms by which they modulate the complex molecular events occurring in xylogenesis.

The *Geneglob* project (2006-2010) produced and used a set of genomic tools which, associated with Next Generation Sequencing (NGS) technologies, allowed us to expand the knowledge of the *Eucalyptus* genome by focusing on regions potentially involved in the determination of wood properties, namely pulp yield and lignin content. We first start to characterize two *E. grandis* BAC libraries (1) constructed by the Arizona Genome Institute (with DNA from the clone Brasuz S1 whose genome was sequenced recently by the DOE [http://www.jgi doe.gov/sequencing/why/99176 html], and two *E. globulus* BAC libraries made available by RAIZ [http://www raiz ilfp pt]). We than used 3D-pools of BAC libraries and BAC macroarrays to characterize genomic environment of several lignin and lignin-regulator genes (e.g. *EucCORM*, *EucCAD2* and *EurAC1*) both in *E. grandis* and *E. globulus*. The shotgun sequencing of selected BAC clones containing those genes generated a high amount of sequencing data that made it possible to map the *E. globulus* BAC sequenced clones against the *E. grandis* genome (8X coverage). These comparative analyses showed extended colinearly between both genomes, at least in the studied regions. Additionally, we have sequenced and annotated the chloroplast genome of *E. grandis* (GenBank Accession NC_014570). [1].

A global approach to unravel *E. globulus* transcriptome dynamics has also been included and structured in the *Geneglob* project, aiming at the identification of genomic hotspots of transcription activity. Various *E. globulus* xylem "models" have been considered comprising several paired, contrasting wood forming tissues (provided by RAIZ): i) xylem samples collected along the year (season variation); ii) juvenile and adult individuals of a single genotype; iii) contrasting genotypes for pulp yield. Samples from these tissues were used for transcriptome sequencing using IlluminaHi-Seq technology (miRNA-SEQ). The same *E. globulus* genotype used for both *E. globulus* BAC libraries (a parent tree used in controlled crosses by RAIZ) has been sequenced (pair-end 100bp), and provided the first draft of an *E. globulus* genome. This resequencing data was mapped against the *E. grandis* Brasuz S1 reference genome. Transcriptomic data were also blasted against the gene models annotated in *E. grandis* genome, to evaluate in silico the expression of each gene.

More recently, the microEGO project (2010-2012) started the identification and characterization of *Eucalyptus* globulus microRNAs and their target genes, involved in the regulation of wood formation. The *E. globulus* season variation xylemology "model" was used considered for this project as well as an *E. globulus* reaction wood "model". The latter comprises reaction wood tissues (tension / opposite wood) formed in bent trees at different kinetic times of gravitropic stimulation and control wood (non-bent trees). Small RNA libraries have been generated from those tissues and sequenced using IlluminaHiSeq technology (Small RNAs-SEQ). The sequencing data from both microEGO and Geneglob projects together with a genome wide bioinformatics analysis of *E. grandis* reference genome and *E. globulus* genome are being used for identification of miRNA gene and putative their putative target-genes.

These projects will hopefully constitute an important piece in the assemblage of whole new categories of knowledge and genomic resources for the *Eucalyptus* community, providing insights into the nature of the molecular machinery involved in wood formation and most importantly in the identification of key players determining the variability of wood characteristics and its end-uses.

Acknowledgments: This work has been partially supported by Fundação para a Ciência e Tecnologia (Portugal); PTDC/AGR-GPL/098179/2008, “microEGO – Did you ask for something small? S9. BIOSAFETY, CERTIFICATION AND ECONOMICS OF TREE BIOTECHNOLOGY

O53 Highly regulated but can’t be certified as sustainable. Responsible use principles are bridging the gap for biotech trees

Adam Costanza
Institute of Forest Biotechnology
E-mail: adam.costanza@forestbiotech.org

BMC Proceedings 2011, 5(Suppl 7):O53

Biotech trees are some of the most heavily regulated plants in the world, yet no forest management system certifies the use of them as sustainable. The Responsible Use: Biotech Tree Principles are the first, and
only, set of practices designed specifically for the long-term stewardship of biotech trees. These Principles may serve as a framework that certification systems can use when considering whether biotech trees meet their certification standards.

Responsible use principles were developed to guide the long-term stewardship of biotech trees. As forest biotechnology has taken root and genetically modified trees are being field-tested for biofuels, species restoration, and disease resistance, the need for a set of global guiding principles for responsible use of these trees became apparent. Since this need was not being met by the international forestry certification schemes, the Institute of Forest Biotechnology (IFB) developed the Responsible Use: Biotech Tree Principles in a transparent, stakeholder driven process over nearly three years.

A broad set of stakeholders has set aside the issues of whether biotech trees should be used and created these stewardship principles. The Principles are in recognition that responsibly used biotech trees have the potential to benefit society, economies, and the environment in ways that other trees cannot. Central to these Principles are core beliefs that:

- Biotech trees should benefit people, the environment, or both
- Risks and benefits of biotech trees must be assessed
- Transparency is vital and stakeholders must be engaged
- Social equity and indigenous rights are important and must be respected
- Biotech tree use must follow regulations of the appropriate country

Risks and benefits of biotech trees must be assessed in studies from all tissues using a variety of techniques. Wildtype American chestnut s reflect that it is necessary to assess any non-target impacts of transgenic plants on native organisms. Gene expression study results based on qRT-PCR indicate that transgenic American chestnut to determine if introduced genes have any associated microbial communities. C. parasitica is a fungal pathogen, so we are particularly interested in studying the effects of any transgene on the symbiotic relationship between the host plant and mycorrhizae-forming fungi. Prior studies have examined the potential impact of transgenic plants on ectomycorrhizal fungi (K. L. Oliver, 2008, Applied and Environmental Microbiology, 74, 5340-48).

**Objectives:**

1. Analyze and compare transgene expression in root, stem, and leaf tissue in American chestnut trees transformed with a gene for oxalate oxidase.
2. Assess potential non-target impacts on mycorrhizal fungi by comparing ectomycorrhizal associations with wildtype American chestnut and a transgenic American chestnut expressing a gene for oxalate oxidase.

**Methods:**

Wildtype American chestnut seeds and transgenic American chestnut (‘Darling4’) trees were grown in a potting mix containing field soil in a soil bioassay to bait for mycorrhizal fungi. All trees were grown in a greenhouse for at least one year before mycorrhizal root tips were harvested. The root system of each tree was rinsed over a fine sieve, and segments of root were collected. Mycorrhizal root tips were quantified and grouped based on morphotype. Fungi were identified using RFLP and sequence analysis of the fungal ITS region.

RNA was extracted for gene expression studies from all tissues using a CTAB extraction method. RNA samples were then DNase treated and used to synthesize cDNA, which was used as a template in all subsequent quantitative RT-PCR experiments. qRT-PCR studies were conducted to determine the relative level of transgene expression in leaf, stem, and root tissue in ‘Darling4’ trees.

**Results:** Gene expression study results based on qRT-PCR indicate that the oxalate oxidase gene is expressed in root tissue of ‘Darling4’ American chestnut and not in the wildtype control (Fig. 1). Transgene expression results for both stem and leaf tissue are comparable to that found in root tissues.

Based on mycorrhizal tip quantification for transgenic and wildtype American chestnut, it appears that there is not a significant difference in total percent fungal colonization between these tree types (Fig. 2). **Discussion and conclusions:**

The results of the gene expression portion of this study show oxalate oxidase is expressed in the root tissue of ‘Darling4’ transgenic American chestnut trees. As expected, there is no oxalate oxidase expression in root tissue of wildtype American chestnut trees. Oxalate oxidase expression in root tissue has the potential to influence associated microbial communities, specifically mycorrhizal fungi that are in direct contact with chestnut roots. It is therefore necessary to assess mycorrhizal associations in transgenic chestnut to determine if there are any non-target impacts as a result of this expression. Mycorrhizal root tips were quantified for both the Darling 4 transgenic chestnut and the wildtype. The results of the total percent ectomycorrhizal fungal colonization portion of the study show that there is no significant difference in overall levels of mycorrhizal abundance between the two tree types. It can be inferred from this that American chestnut trees expressing mycorrhizal enzymes are able to form mycorrhizal associations in a similar manner to the wildtype.

As with any other transgenic plant, ‘Darling4’ and other transgenic American chestnut trees are required to go through extensive deregulation procedures before they can be released back to the native chestnut range. The results from this study will be used in conjunction with other ecological impact studies to inform the deregulation process in.
an effort to restore the American chestnut. This study will also contribute to a body of existing work examining the potential environmental impacts of transgenic forest trees that can inform future policy and procedures relating to the genetic modification of important species.

**O55** Mycorrhization of transgenic apple trees with increased resistance against fungal pathogens

**BMC Proceedings** 2011, 5(Suppl 7):O55

The project ‘Mycorrhizal symbioses of transgenic apple trees with increased resistance against fungal pathogens’ (Subproject of the framework ‘Biosafety of transgenic woody plants’, supported by the German Federal Ministry for Education and Research) investigates whether the transformation of apple trees with fungal chitinase encoding genes - besides increasing resistance against fungal pathogens - also interferes with mycorrhizal fungi. Pathogenic fungi such as the ascomycete species *Venturia inaequalis*, the pathogenic agent of apple scab, cause severe damage in apple cultivation. In commercial apple production, pesticides are employed frequently and in high quantities. Alternative methods such as the use of mycoparasitic *Trichoderma* fungi to control fungal plant pathogens have been explored [1]. Genetic engineering of apple cultivars with *Trichoderma* chitinases has lead to an increase of the trees’ resistance against apple scab [2]. However, like many fruit tree species, apple trees form symbiotic associations with arbuscular mycorrhizal fungi (AMF) at their roots. AMF receive fixed carbon compounds, while the plants benefit from the symbiosis by enhanced uptake of nutrients and water, promoted growth, and increased resistance against biotic and abiotic stress [3]. Like in most higher fungi, the cell walls of AMF contain chitin as a major skeletal component [4]. Consequently, the symbiosis between apple and AMF may be negatively affected by the expression of *Trichoderma* chitinase genes within the plant. At the Julius Kühn-Institute in Dresden, the apple cultivar ‘Pinova’ was transformed by introducing the construct pBIN (Endo + Nag) into the transgenic lines. With the help of promoter CaMV 35S the transgenic lines constitutively express endochitinase gene *ech2* and exochitinase gene *nag70* from the bioccontrol fungus *Trichoderma atroviride*. In order to study whether the constitutive expression of *ech2* and *nag70* has an effect on mycorrhization of plants with transgenic roots (local effect) and – as apple cultivars are propagated vegetatively by grafting – whether expression of *ech2* and *nag70* in a transgenic scion grafted on a non-transgenic rootstock has an effect on mycorrhization (systemic effect), a series of greenhouse experiments was conducted. In a first experiment, non-grafted clones of wildtype apple cultivar ‘Pinova’ and two transgenic lines were cultivated in artificial substrate and inoculated with two AMF species, *Glomus intraradices* and *G. mosseae*. After four months of cultivation, root colonization rates were determined. In a second experiment, grafted sample trees were inoculated with two AMF species from an extensively managed plantation in the ‘semi-natural’ environment of a gossamer cage. Root samples were taken after 12 and 24 months. For all experiments, root colonisation rates were determined microscopically. Molecular methods – PCR with taxa specific primer sets [6], cloning of PCR products, Sanger sequencing – were applied to study the impact of the transformation on the composition of the fungal communities associated with the roots of the sample trees cultivated in soil. Chitinase activity in leaves and roots of sample trees was determined using fluorescence spectrometry and substrates 4-methylumbelliferyl N-acetyl-β-D-glucosaminide for exochitinase and 4-methylumbelliferyl β-D-N,N,N′-triactylchitotrioside for endochitinase activity. The results of this biosafety research concerned with potential adverse effects on beneficial soil fungi will be presented and discussed.

**BMC Proceedings** 2011, 5(Suppl 7):O56

**Background**: Lignin is one of major components of plant secondary cell wall. In plant cell wall, it is synthesized via radical coupling of precursors such as p-coumaryl, coniferyl, and sinapyl alcohols. In early stage of the lignification, 8-0-4’, 8-’8- and 8-5’ dimers are thought to be synthesized mainly from the precursors in the wall. A gram-negative bacterium,
**Shingobium** sp. strain SYK-6 (hereafter refer to as SYK-6) is able to catabolize a wide variety of phenolic compounds including the lignin precursors by its unique enzymatic system. One of catabolic enzymes, LigD, catalyzes oxidation at alpha (benzy) position of 8-O-4’ dimers and forms carbonyl group at the position (Figure 1). This oxidation is the first step of catabolic pathway of 8-O-4’ dimers in SYK-6. When we express LigD polypeptide in the cell wall of transgenic plants, the oxidative dimers will be expected to be generated and then incorporated into lignin polymer. In some past studies, it has been shown that the presence of carbonyl groups at the alpha position of aryl propane units in lignin greatly speeds up the rate of cleavage of beta-aryl ether linkages during kraft pulping condition [1,2]. In order to contribute to efficient and sustainable production of kraft pulp and the other biomass-derived products such as bioethanol, we introduced the ligD gene into *Arabidopsis* and hybrid aspen and tried to generate transgenic plants whose lignin can be easy to remove from holocellulose fraction under alkaline conditions.

**Method:** Because of the codon usage is significantly different between genes in plants and SYK-6, we chemically synthesized open reading frame (ORF) of the ligD gene for improving its expression in the transgenic plants. After addition of nucleotide sequence for apoplast-targeting signal peptide to the synthesized ligD ORF, it was introduced into Arabidopsis thaliana, tobacco BY-2 and hybrid aspen under the control of cauliflower mosaic virus 35S promoter. LigD expression in the transgenic plants was monitored by Western blot analysis and enzymatic activity with crude extract prepared from each transgenic line. Preliminary analysis of lignin structure by 2D-NMR and nitrobenzene oxidation was also performed.

**Results and discussion:** At first we confirmed expression of the ligD transgene in Arabidopsis by Western blot analysis with antisense against LigD polypeptide. Positive expressions of the ligD were detected in some of the transgenic plants analyzed. Enzymatic activities of LigD in crude extracts prepared from both cytisolic and apoplastic fractions of the transgenic Arabidopsis plants were also detected, but it was relatively higher in the latter case. As expected, 2D NMR (1H-13C HMQC) analysis suggests that the abundance of the alpha-keto (alpha carbonyl) structure in 8-O-4’ units of lignin in the transgenic plants is relatively higher than that in the wild-type plant. Chemical compositions of lignin (syringyl/guaiacyl ratio) and neutral sugars could not be distinguishable between the transgenic and wild-type plants. Generation of transgenic hybrid aspen and its analysis are now in progress.

**Acknowledgements:** This research project was supported partly by the New Energy and Industrial Technology Development Organization (NEDO).

BMC Proceedings 2011; 5(Suppl 7):O57

Motivated by the Brazilian Ministry of Agriculture, Farming and Supply (MAPA), we created in 2009 the “Collaborating Center in Agriculture Defense Relative to the Biosafety of Genetically Modified Eucalypts” (Project “CDA Eucalyptus”) in order to collect information and conduct research to assess the biosafety of GM eucalypts in the Brazilian context. The Normative Resolution Nr. 5 of the National Biosafety Technical Commission (CTNBio) is the official document presenting all information needed to propose the commercial release of GMOs in Brazil. Based on this document and along with the personnel of the Suzano Paper & Cellulose Co., we conducted a series of experiments with GM and non-GM eucalypts planted in a test field in the state of São Paulo to start collecting the necessary information. Two independent groups of transgenic plants, harboring two different transgene constructions along with non-GM control plants are being assayed. The genetic traits, the identity or names of the transgens as well as the identity of each tree individual will not be revealed due to intellectual property request still pending. Each group of plants was represented by four independent events in triplicates (2 groups x 4 events x 3 clonal trees = 3 non-GM clonal trees), therefore totaling 27 individuals under analysis. Samples were identified by random numbers and all assays were conducted in a simple-blind or a double-blind fashion. Tests conducted until now included (i) the detection of transgene regulatory sequences in purified DNA samples by conventional PCR and RT-qPCR, confirming the expected sampling conducted; (ii) extraction, chemical characterization and analysis of the antifungal effects of essential (volatile) oils extracted from leaves; (iii) pollen germination in vitro; (iv) flower morphology; (v) seed production; (vi) initial seedling development; (vii) leaf allelopathy; (viii) measurements of total phenolic compounds in leaves and roots; and (ix) effects of leaf extracts on the viability of human colon cells. All results obtained from experiments (ii) to (ix) revealed no statistical differences between GM- and non-GM-derived samples. A second round of experiments will be conducted to confirm these results. Proteomic and transcriptomic profiling of GM and non-GM trees are under analysis, as well as a series of experiments that include the chemical, nutritional and biological analysis of honey samples derived from bee hives located in fields of GM versus non-GM plants; and bee (Apis mellifera) population dynamics.

**BMC Proceedings** 2011, 5(Suppl 7):058

In the last 20 years, a large number of GMTs have been generated, characterized and field tested to evaluate their agronomic behaviour and their potential performance for technological applications.

Therefore, important knowledge has been gained from these studies on the potential of GMTs whereas biosafety concerns have been raised on the plantation of transgenic trees in the field. The European Cooperation in Science and Technology (COST) action FP0905 on the biosafety of forest transgenic trees aims to help forth building and implementation of EU policy directives to ensure a safe development and practical use of GMTs in the future. This Action is expected to generate important benefits thanks to the experience gained by the research community, to provide general information on these studies as well as to address public concerns about biosafety issues raised by transgenic tree plantations, and finally to help for the establishment and implementation of EU policy directives in the view of a future deployment of GMTs cultivation in Europe. Within this action, the objective of the working group 1 (WG1) is to gather the existing knowledge on genetically modified forest trees (GMTs) including both field trials and greenhouse experiments. More specifically, the action of WG1 is focused on the compilation of:

- Data from literature and methods developed on gene flow and containment strategies
- Data available on the traits targeted and the function of the gene introduced, on their intended and eventually unintended effects
- Data on host species characteristics related to biosafety issues such as their biological cycle, their way of pollination and the characteristics of pollen and seed dispersal.

This information will be collected from published papers in books and reviews as well as from reports from different agencies available on the web. Moreover, additional data will hopefully be gained through the responses of expert scientists from public or private institutions to an ongoing survey accessible at the website of the COST Action FP0905: [http://www.cost-action-fp0905.eu/index.php?option=com_kunena&func=view&catid=4&id=11](http://www.cost-action-fp0905.eu/index.php?option=com_kunena&func=view&catid=4&id=11)

The information collected will be used to:

- 1) establish a list of protocols for the control of transgene flow and gene containment.
- 2) establish the present state of the art in gene targeting strategies for site specific integration of transgenes.
- 3) get an appraisal on the types of construct and genes inserted in GMTs in the past; in the present and in the future.

This information will be compiled in a database that will be made available to the scientific community as well as to the European policy makers.

The results of this work will enable the participants and end-users to get a clear factual overview of the global status of GMTs and especially the status of Europe compared to non-European countries. Furthermore, the information gathered will also be useful for assessment of environmental impacts of GMTs that is the object addressed in the WG2 of the COST Action FP0905.

---

**BMC Proceedings** 2011, 5(Suppl 7):09

Transgenic biotechnology can assist forest tree improvement programs but it may also raise environmental safety concerns. The environmental effects of genetically modified transgenic trees (GMTs) have been studied in many countries during the last 15 years. Today there is an urgent need of putting together this scattered knowledge to build-up a European knowledge platform for addressing GMTs in plantations. The main aims of Working Group 2 (WG2) of the European Cooperation in Science and Technology (COST) Action FP0905 “Biosafety of transgenic forest trees” ([http://www.cost-action-fp0905.eu/](http://www.cost-action-fp0905.eu/)) are (1) to discuss, based on scientific facts, whether current containment strategies are appropriate or need to be improved for GMTs, (2) to define a common protocol to track the transgene from the laboratory to the final product, and (3) to assess the possible impacts of GMTs on the environment. The potential risks of GMTs, the fate of recombinant material and the potential relevance of recombinant genes on plantâ€™s omics are other main aspects to be considered and compared to similar processes with endogenous genes in conventional breeding. The group involves experts from public research, government and independent regulatory sectors across COST and non-COST member countries. The activities of this group have been organized into three Task Groups focusing on (1) risk assessment studies and guidance documents, (2) the monitoring of the transgenes and recombinant plant material, and (3) the impact of GMTs on exposed ecosystems. As a first step of WG2 activity, a database of guidance documents from national and transnational sources dealing with impacts and risk assessments of GMTs is being created to identify common and case-specific issues on biosafety. It is expected that the information collected will facilitate (1) a science-based understanding of the impacts of GMTs on the environment in comparison with that of traditionally tree breeding, and (2) future socio-economic and cost/benefits analyses of GMTs in plantations.

**BMC Proceedings** 2011, 5(Suppl 7):060

**Background:** The Cost Action FP0905 aims to evaluate the scientific knowledge of GMT biosafety protocols coordinating the existing information generated in various European countries as basis for future EU policy and regulation for the environmental impact assessment.
For spreading the information relevant to the Action, the website http://www.cost-action-fp0905.eu/ has been set up, educating the general population of the technical, social, environmental and economic aspects of this issue. The principal aims of the website are: to provide a database with the main information on forest GMTs, that should be available to the scientific community and Europe organisations; to update the website with science-based information for public interest in the utilization of GMTs in forest plantation and at the same time safeguarding the environment, using all the information collected to identify particular topics which could be useful to develop research projects collaborating with the other working groups.

**Material and methods:** The Website was built using the Open Source Software Joomla, a program for web site design and content management. This software has not been written for profit, but to benefit the user community. The difference between Joomla and other web design software systems is that there are thousands of fully functional, complete web site templates available in the Internet, so that all what is to do is to choose the layout you like and to add information in the templates.

However, Joomla as a “Content Management System” is not only a “simple” web site construction program, furthermore it can also be used as a database. It is used to build/design a “php/mysql database” to...
Field trials of GM trees in the USA: activity and regulatory developments

Steven H Strauss, Venkatesh Viswanath
Department of Forest Ecosystems and Society, Oregon State University, 321 Richardson Hall, Corvallis, OR 97331, USA
E-mail: Steve.Strauss@oregonstate.edu
BMC Proceedings 2011, 5(Suppl 7):O61

Field trials are extremely important for all facets of research, breeding, and biotechnology. Tree physiology is distinctively different in greenhouses or growth chambers vs. field environments. Thus, results from non-field environments can be very misleading with respect to identification of promising biotechnologies and elite varieties. Large regulatory impediments to conduct of field tests of genetically modified (GM) trees will therefore tend to stifle scientific and technological development. This appears to be the case for genetically modified trees, where regulatory burdens to conducting field tests have grown in stringency in the USA and elsewhere in recent years [1,2]. Here, we present the record of recent field trials and some new regulatory developments in the USA.

Overview of field trials in the USA: Information Systems for Biotechnology (ISB) [3] maintains an easily used database of GM crop data in the United States. There have been nearly 600 field trials (including both “acknowledgments” and “permits”) conducted since 1989, with a five-fold increase occurring in 2000-2009 compared with 1990-1999 (Figure 1).

Fifteen different genera have been tested, including Populus, Pinus, Eucalyptus, and Malus, with the first two accounting for approximately 60% of all field trials (Figure 2). Marker genes and tolerance to biotic stresses were the two most common research objectives. Private companies carried out 60% of field trials, and their activity has grown dominant in recent years.

Currently, there are more than sixty field trials covering eleven different genera, with Populus accounting for 35% of all field trials. Eucalyptus, Liquidambar, and Malus together account for another 37% of trials. Other genera being tested include Castanea (American chestnut), Pinus, Ulmus (American elm), Prunus, Musa, Citrus, and Juglans. Forty field trials are being conducted by private companies, with ArborGen alone accounting for 36 of the 40 active field trials. Cornell University, North Carolina State University, Oregon State University, Purdue University, the United States Department of Agriculture (ARS) and the University of California, Davis are among the public institutions currently conducting field trials. One of ArborGen’s field trials with cold tolerant Eucalyptus covers 197.2 acres. This is the largest current field trial in terms of acres and is being conducted in six different states. In terms of research objectives of current trials, marker genes dominate in terms of frequency of trials, with modification of wood quality the next most common objective.

Regulation of field trials in the USA: In the USA, transgenic trees are regulated in the same manner as agricultural crops [4], using regulatory laws created prior to the development of transgenic biotechnology. The three agencies involved are the United States Department of Agriculture (USDA), which considers agricultural safety and economics; the Food and Drug Administration (FDA), which considers human and animal feed safety; and the Environmental Protection Agency (EPA), which considers pesticidal properties of transgenic organisms [5]. Regulations in the United States are perceived to be less stringent than those in Europe and Asia, however, a recent survey in the USA found that forest scientists—including breeders, biotechnologists, and ecologists—see regulations as major obstacles to field research and commercial development of GM trees [6].
Recent regulatory developments: A company known as Okanagan Specialty Fruits has taken the lead in the production of transgenic tree varieties produced by the insertion of cisgenes and intragenes [7]. Non-browning versions of established apple varieties were developed by the company by the silencing of the polyphenol oxidase gene. These apples have been named Arctic™ apples because of the color of their skin. The company has petitioned the Animal and Plant Health Inspection Service (APHIS) for deregulation of the product in the USA [8]. Cold tolerant eucalyptus varieties were developed by ArborGen [9]. The company believes that these varieties would permit the planting of highly productive eucalypt hybrids for bioenergy and pulp north of Florida in the USA. In May 2010, the USDA authorized a large scale flowering field trial of these trees, thus permitting the planting of nearly 260,000 trees over ~300 acres in 7 states [10]. However, several environmental organizations filed a lawsuit against APHIS because they believed that APHIS performed an inadequate environmental analysis, thus violating the US National Environmental Policy Act (NEPA). A new two year pilot project has recently been announced by APHIS [11]. Under the provisions of the new project—whose aim is to speed up the review process before deregulation of biotech crops—environmental assessments of transgenic crops will be conducted by companies themselves, or by contractors authorized by the USDA. Although USDA would still need to review and approve the analyses, critics of the new policy believe that it might lead to less stringent environmental analyses.

Research in tree genetic engineering; the Canadian context for field trial of GM trees
Armand Séguin
Natural Resources Canada, Canadian Forest Service, Laurentian Forestry Centre, Canada
E-mail: armand.seguin@nrcan.gc.ca

BMC Proceedings 2011, 5(Suppl 7)O62

Canada is in a unique position for the regulation of GM (genetically modified) plants since it is based on the novelty of the resulting traits and not on the process to obtain it. For this reasons the term “plant with novel traits” (or PNTs) is used and these traits can be introduced into plants using biotechnology, mutagenesis or conventional breeding techniques. In Canada, less than a handful of GE tree field trials have been conducted. In all cases, poplars or spruces were used. Consistent with international guidance provided for living modified organisms, particular attention is given to a specific trait by considering both its novelty for the Canadian environment and its potential effect on human health and the environment. Our research is in line with the development of a consolidated research approach and knowledge needed for international guidance (e.g. Cartagena Protocol on Biosafety under the Convention on Biological Diversity) developed for genetically modified organisms. Important losses due to insects and fungal pathogens result in a considerable reduction of yield in Canadian forest productivity. Compounding these problems is the increased movement of pests that has been facilitated by increased international trade of agricultural and forest products as well as global climate change. More recently the increased need for biomass production and specific bioproducts to sustain crop-based biofuel production has emerged. Forest biotechnology...
has the potential to maintain forest sustainability by contributing to the transformation of our forest industry so as to improve productivity in the context of tree plantation. In this presentation, we will show how genetic engineering of forest trees has been used in improving tree adaptation and pest protection. We will also describe the work being done on environmental assessment of field-grown trees and results on long-term expression of engineered genes.

O63 A brief overview of field testing and commercial application of transgenic trees in China
Meng-Zhu Lu1, Jian-Jun Hu2
State Key Laboratory of Forest Genetics and Tree Breeding, Chinese Academy of Forestry, Beijing 100091, China
E-mail: luru@caf.ac.cn
BMC Proceedings 2011, 5(Suppl 7):O63

Since the first report on transformation of Bt gene into Populus nigra was published in 1989, transgenic approaches have been widely used in breeding trees for high tolerance to insects and environmental stresses in China. Notably, field testing of the transgenic poplar with Bt was performed in 1994 and permitted to be commercialized as the first commercialized transgenic tree in the world. Up to now, nearly 50 species have been used as recipients for genetic transformation including poplar, birch, locust tree, walnut, aimed to improve their tolerance to insects and diseases, environmental stresses, prolonged storage lifetime, wood property, flowering time control, etc.

On May 5, 2006, the State Forest Administration (SFA) launched its first regulatory framework on “Management measures on the inspection and permit of forest genetic engineering” taken effect on July 1, 2006. It states that small-scale field testing, environmental release and pilot production test of each transgenic line are required before its permit of commercialization, with each phase must be evaluated by the experts. “A technical guideline on safety evaluation of the transgenic forest plants and their products” was published by SFA on June 4, 2007, which provides a standard procedure for molecular breeders to follow in order to commercialize their transgenic trees.

To the year 2010, 128 field trials have been granted by SFA, 84 of which belong to tree species while 44 to grass species. Thirty three of them were granted to transgenic poplars, with tolerance to insects and diseases, drought and salt stresses, altered wood property, etc., and 25 to locust tree. Transgenic Populus tomentosa with antisense CaCoAMT (coding for a key enzyme involved in lignin monomer biosynthesis), transgenic Robinia pseudoacacia with BDAH, Sophora japonica with RD29A and P. nigra with Bt are under environmental release testing. The transgenic poplar plantation has increased to 450 hm²; this year since two Bt transgenic poplars were commercialized in 2001 in China. The transgenic poplar plantations have effectively inhibited the fast-spread of target insects and significantly reduced the times of insecticide application on poplar plantation. The transgenic Populus nigra was also used in hybridization with non-transgenic P. deltoides as an insect-resistant source for breeding new hybrid clones.

S1. POPULATION GENOMICS, CONSERVATION AND ADAPTATION

P1 Identification of microsatellite loci in Pinus tecunumaniil

E-mail: ananda@cnpf.embrapa.br
BMC Proceedings 2011, 5(Suppl 7):P1

Background: Pinus tecunumaniil has displayed good performance in tropical regions of Brazil and showed high potential for commercial exploitation. Embrapa Forestry and its partners own many of the species seed production areas. In spite of its importance, the majority of P. tecunumaniil germplasm collections remain still genetically uncharacterized. Thus identifying genetic markers is an important tool to genetically characterize these collections. We describe the initial steps to develop microsatellites for Pinus tecunumaniil by enriched library construction with the ultimate goal of characterizing accessions of the germplasm collections of EMBRAPA.

Methods: The genomic-enriched library was constructed following the protocol described by [1]. The genomic DNA of P. tecunumaniil was digested with AFLP and enriched in (CT) and (GT) repeats. Enriched fragments were amplified by polymerase chain reaction (PCR), connected to a pGEM T-easy vector and transformed into competent XL1-blue Escherichia coli cells. The positive clones were selected using the B-galactosidase gene and then grown overnight in an HM/F medium with ampicillin. After PCR 95 positive clones were sequenced in both directions using the T7 and SP6 primers as well as the Big Dye terminator Kit. The sequences were assembled and edited in Seqman (DNASTar), the repetitive regions were found using the Simple Sequence Repeat Identification Tool [2]. Primer select (DNASTar) and Primers Plus were used to design primer pairs flanking the microsatellite regions.

Results and conclusion: Of the ninety five sequences cloned only eleven contained microsatellite sequences and five showed repeats and adequate flanking regions for primer design. The observed proportion of dinucleotide was 5.26% (S), while trinucleotide and tetrinucleotide proportions were 1.05% (1) and 5.26% (S), respectively. Ninety one percent of nucleotides were simply perfect and 9% were compust perfect. The explanation for this low yield (11.6%) can be attributed to the genomic-enriched procedure. To overcome this problem this procedure will be repeated. The obtained sequences will be used for validation of P. tecunumaniil microsatellite primers and used to estimate the genetic diversity from the germplasm collection located in various regions of Brazil.

Acknowledgments: The authors would like to thank Selma Buzzetti de Moraes and Mario Luiz Teixeira de Moraes for their assistance with DNA extraction procedures and the Valor Florestal Company for collecting material used in this research.

E-mail: ananda@cnpf.embrapa.br
BMC Proceedings 2011, 5(Suppl 7):P2

Background: Integrating the use of molecular techniques in ongoing breeding can help identifying divergent genotypes to be used in controlled crosses for the development of hybrids, estimating parentage and monitoring the efficient use of genetic variation. Breeding programs carried out at EMBRAPA have established a broad population genetic base for various species of pine, from which trees with high productivity and wood quality have been selected. P. maximinoi was included in this program as its timber has specific characteristics of great economic importance. One of the main features of P. maximinoi is its rapid growth, reaching 20 to 40 meters in height with a diameter at breast height of 100 cm. The species' straight trunk with few branches is advantageous to the sawmill, and the timber's thick fiber is necessary for quality paper production. In this work we report on the initial steps of the development of microsatellite markers for P. maximinoi derived from

References
microsatellite-enriched libraries. These markers will be used to characterize the breeding populations and germplasm collections of EMBRAPA.

Methods: A microsatellite-enriched genomic library was constructed following the protocol described by [1]. The genomic DNA of *P. maximinoi* was digested with AFAI and enriched for two microsatellite motifs (CT)\(_n\) and (GT)\(_n\). Enriched fragments were amplified by PCR, ligated to a pGEM T-easy vector and transformed into competent XL1- blue *Escherichia coli* cells. The positive clones were selected using the 8-galactosidase gene and then grown overnight in an HM/F medium with ampicillin. After PCR, 88 positive clones were sequenced in both directions. The sequences were assembled and edited in Seqman (DNASTAR), and the repetitive regions were found using the Simple Sequence Repeat Identification Tool [2] Primer select (DNASTAR) was used to design primer pairs flanking the microsatellite regions.

Results and conclusion: Of the eighty sequences cloned only eight contained microsatellite sequences showing repeats and adequate flanking regions for primer design. The observed proportion of dinucleotide was 6.81\%, while the tetranucleotide proportion was 22.70\%. Seventy five percent of nucleotides were simple perfect repeats and 25\% were compost perfect. The explanation for this low yield (9.09\%) can be attributed to the genomic-enriching procedure. To overcome this problem the procedure will be repeated. The obtained sequences will be used for validation of *P. maximinoi* microsatellite primers. Eight microsatellite sequences of simply perfect and compost perfect nucleotides were observed for *P. maximinoi*. These markers will be validated and used to estimate the genetic diversity from the germplasm collection of the Brazilian Agricultural Research Corporation (EMBRAPA).

Acknowledgments: The authors would like to thank Selma Buzzetti de Morais and Mario Luiz Teixeira de Morais for their assistance with DNA extraction procedures and the Valor Florestal Company for collecting material used in this research.

**BMC Proceedings** 2011, 5(Suppl 7):P3

Conifers, like other perennial plants adapt their growth rhythm to seasonal changes in the environment. Growth cessation and bud set are among the main adaptations used by the plants to prepare for winter. These adaptive traits are mainly controlled by photoperiod, temperature and light quality and show a clinal variation in different species including Scots pine. In conifers, efforts have been made to understand the genetic basis of these traits. In Norway spruce for instance, a *Flowering Locus T* homolog (PaFt4) has been shown to be implicated in the control of growth rhythm. We previously evaluated genetic variation for timing of bud set and cold tolerance in a large association population of Scots pine (*Pinus sylvestris* L.) from Punkaharju, Southern Finland, along with five other populations used as control for clinal variation. To correlate this genetic variation with the expression pattern of some candidate genes already described in other species including conifers as involved in the control of bud set (e.g. FTA4, PRR1, GI, Myb) and cold tolerance (e.g. Aba responsive, DHN3, ERD, LEA), the Punkaharju population was used together with two others from Kolari (Northern Finland) and Poland. For photoperiod treatments, seedlings of eight families from each population were grown in a greenhouse under natural photoperiod conditions and in growth chambers under constant light for three months before transfer to three different photoperiod conditions (20 h/4 h, 17 h/7 h and 8 h/16 h light/dark). For cold treatments, the same families were grown in growth chambers under constant light for two and a half months and divided into two parts. The first part was directly submitted to the cold treatments (+4°C for one week followed by -5°C for 48 hours) while for the second part, seedlings were allowed to set buds under short day conditions (8 h light/16 h dark) before treatments. The results of this expression study will be described in relation to the phenotypic variance already observed.
Genetic diversity of *Bertholletia excelsa*, an Amazonian species of wide distribution

Patricia Sugi, Karina Martins, Luciana Wacht and Vânia Azevedo

1Laboratório de Diversidade Genética, Universidade Estadual de Campinas, Campinas, Brazil; 2Universidade Federal de São Carlos, Brazil; 3Embrapa Acre, Brazil; 4Laboratório de Genética Vegetal, Embrapa Recursos Genéticos e Biotecnologia, Brazil; 5E-mail: vania.azevedo@embrapa.br

**BMC Proceedings 2011, 5(Suppl 7)5P5**

**Background:** Amazonian upland forests are expansive and can comprise large continuous tracts. There have been several studies on the population genetic structure of species in this kind of forest, but there are few studies that aim to understand genetic structure throughout the Amazon [1]. The Brazil-nut tree, *Bertholletia excelsa*, is a monotypic genus, endemic to upland forests and distributed along almost the entire expanse of the Amazon [2-5].

Genetic diversity distribution through Amazon forest is an understudied issue, specially in plants. Quantifying and understanding population genetic structure, associated to gene flow and mating system studies are recognized as important tools for the development of strategies for conservation and management. Such information can also be helpful in identifying effects of habitat fragmentation [6,7].

This study aimed to evaluate genetic structure of *B. excelsa* populations in the Amazon and to verify if the structuring is influenced by distance between them.

**Methods:** Seven polymorphic microsatellite markers were developed from a dinucleotide-enriched genomic library. Material from 379 individuals was collected from nine Amazonian subpopulations distributed in five Brazilian states (AC: Acre; AM: Amazonas; AP: Amapá; PA: Pará; RR: Roraima). All seven microsatellite markers developed for the species were used with four others previously published markers [8], for genotyping.

Analyses within and among populations were performed to evaluate genetic diversity and population structure. All nine populations were characterized with 11 microsatellite loci for number of alleles per locus, allele frequency and observed and expected heterozygosity under Hardy-Weinberg expectation. Wright fixation indices were also estimated. Genetic distance estimates were correlated with different potential factors to find possible causes of genetic structure.

**Results and Conclusions:** A few alleles were found in each subpopulation and considerable variation was observed in alleles found in each subpopulation and in their allele frequencies, especially when compared with very distant subpopulations. Heterozygote excess was observed in five subpopulations while in the other four subpopulations, estimates of F$_{st}$ non-significantly different from zero, were found. The observed high heterozygote proportions in most subpopulations and absence of inbreeding support the existence of self-incompatibility mechanisms and selection in favor of heterozygotes. Maintenance of genetic variability is favored by the alogamous breeding system, which is an important feature to be considered in conservation and management strategies, in order to avoid fertility deficits.

Fine-scale structure, when present, was small. Estimates of inter population genetic structure varied from low (r=0.02) to high (r=0.244). *B. excelsa* genetic structure can be analyzed on three different scales: (i) within population; (ii) among moderately distant populations (<500km); and (iii) among very distant subpopulations. At all scales, significant correlations were found between genetic structure and geographic distance between pairs of individuals or populations. This may indicate that distance is an important factor in this population's genetic structure, but probably there are other factors acting in conjunction, especially on a large geographical scale.

Molecular phylogenetics of the genus *Hexachlamys* (*Myrtaceae*) using chloroplast and nuclear markers

Fernanda Cruz, Andrea Turchetto-Zolet, Nicole Veto, Cláudio Mondin, Mauricio Almerado, Rogério Margs

1Programa de Pós-Graduação em Genética e Biologia Molecular, Universidade Federal do Rio Grande do Sul (UFRGS), Brazil; 2Centro de Biotecnologia UFRGS, Brazil; 3Pontifícia Universidade Católica do Rio Grande do Sul, PUCRS, Brazil; 4Centro de Biotecnologia UFRGS, Pesquisador CNPq, Brazil

**BMC Proceedings 2011, 5(Suppl 7)P6**

**Background:** Myrtaceae family includes more than 3,800 species of trees and shrubs, distributed mainly in tropical and subtropical regions of the world. Representatives of this family have great ecologic significance for forest ecosystems, and are economically important species in the pharmaceutical, food, cosmetic and perfumery industry [1]. The genus *Hexachlamys* Berg, (*Myrtaceae*) has about 10 species distributed from the Southern to the Southeast of Brazil, and it also occurs in Paraguay, Argentina, Bolivia and Uruguay [2,3]. Since 1968 it has been considered an independent genus. It is distinguished morphologically from the genus *Eugenia* by pentameros or hexameros flowers and exserta radicle, and as many genera and species of the Myrtaceae family, it has a complex taxonomic classification [4,5]. The goal of this study was to conduct a molecular phylogenetic analysis among species of the genus *Hexachlamys* (*Myrtaceae*) using chloroplast (cDNA) and nuclear (rDNA) markers, and to verify its phylogenetic relationships with the genus *Eugenia* in order to contribute to the systematics and taxonomy of it.

**Methods:** The samples were collected as leaf material (from herbaria species and samples collected in the field) of the genus *Hexachlamys* representing all described species, as indicated in herbariums and species of the *Eugenia* genus that occur in the Rio Grande do Sul state. Total genomic DNA was extracted using the CTAB method based on the protocol already described [6] and used for the PCR reactions. PCR products were sequenced on ABI PRISM 3100 sequencer (Applied Biosystem). Nucleotide sequences were aligned using CLUSTALW [7] implemented in MEGAS (Molecular Evolutionary Genetics Analysis) version 5.0 [8], then checked visually and carefully improved manually before analysis. The phylogenetic analysis was reconstructed after nucleotide sequence alignments using three different approaches: the neighbor-joining (NJ), the Bayesian and the Maximum-Likelihood (ML) methods. The NJ, Bayesian and ML analysis were performed in MEGA 5.0, MrBayes [9] and PhyML [10], respectively.
Results and conclusions: To date we obtained DNA sequences of 21 species of the genus Eugenia and seven species of the genus Hexachlamys. Universal primers that amplify chloroplast region (trm-trnF, trnL-intron, ycf5, accD, rbcL, psaA-trnH, rpoB, rpoC1, ndhJ, matK and rps16) and nuclear (ITS) were tested. The regions used for the phylogenetic analyses were chloroplast accD, rpoB, rpoC1 genes and the nuclear ITS, since the other chloroplast regions were not possible to amplify and sequence in all sampled species. These cpDNA and ndDNA regions presented polymorphisms among species studied. Results from Bayesian, NJ and ML tree analysis produced similar topologies and revealed that Hexachlamys species did not form a monophyletic clade. The Eugenia species have grouped together Eugenia species with high bootstrap values, indicating that Hexachlamys can be a synonymous of genus Eugenia. These results corroborate with morphological data [11]. To confirm these results, other cpDNA and ndDNA markers will be tested and Hexachlamys species will be collected to substitute the species obtained in herbarium, since we found difficulties in the amplification of these species with all markers previously tested. This study can contribute to taxonomic classification of this group, as well as the field of conservation, since these species have an important economically and ecologically role.

E-mail: ronai1977@yahoo.com.br

BMC Proceedings 2011, 5(Suppl 7):P7

Background: Aspidosperma polyneuron (Apocynaceae), commonly known as peroba-roxa, is a native and perennial species characteristic of semideciduous forest in submontane formation of Atlantic rain forest [1]. This species is recommended for ecosystems recovery and restoration of riparian forests in areas without flooding. But, the crescent logging, agriculture and urban expansion caused the reduction of native population of A. polyneuron. It is now included in the Red List of Threatened Species [http://www.iucnredlist.org/apps/redlist/details/32023/0]. Little is known about the population structure of A. polyneuron and the effects of the spatial isolation on the levels of genetic diversity and gene flow. In this study, we developed microsatellite loci for A. polyneuron aiming future studies of genetic structure, gene flow and mating system.

Material and methods: Genomic DNA was extracted from leaf tissue [2] from one individual located in Cravinhos Municipality, São Paulo state, southeastern Brazil (21°17'41.8'S; 47°42'08.5'W). The Microsatellite-enriched library was constructed using the protocols described earlier [3]. The DNA was digested with RviI, bound to the adapters (Rsa21 and Rsa25) and amplified through polymerase chain reaction (PCR). The products were purified by Quiagen PCR purification kit (Qiagen). Fragments containing microsatellite sequences were selected by hybridization with biotinylated oligo-probes (CTn, GTn and CTTn). The amplified DNA was denatured and separated on 8% denaturing polyacrylamide gels stained with silver nitrate. Allele sizes were estimated by comparison by 10 bp DNA ladder standard (Invitrogen) and the original DNA used for library development. FSTAT software ([http://www2.unil.ch/popgen/softwares/fstat.html]) was used to calculate the genetic parameters per locus, allele number, the genetic diversity (Hs) and the linkage disequilibrium. The cumulative exclusion probabilities were calculated by CERVUS 3.0 software [4].

Results and conclusions: A total of 384 clones were obtained and sequenced. Thirty-nine clones (10.2%) presented microsatellite repeats and 25 were suitable for primers design. The most common repeat motif was GA/CT as expected due to the employing technique. Among the loci analyzed, one did not amplify, eight were monomorphic and 16 loci showed polymorphism in this sample. Twenty loci were dinucleotide (83.3%), one was tetra-, other one penta- and two were rare compounds loci: di/tri- (Apn8) and di/tetra- (Apn9). Mendelian inheritance analyses were carried out for each polymorphic locus using one mother tree and their open-pollinated family (26 progeny). All sibs displayed at least one of the maternal alleles, confirming Mendelian inheritance. From a total of 121 alleles presented in the sample, the genetic diversity was high (Hs = 0.65) and the linkage disequilibrium, applying Bonferroni correction for multiple comparisons, was not significant. The total paternity exclusion probabilities over 16 loci were very high for one (P EXCL = 0.9995) or both parents available (P EXCL = 0.9999) indicating that the set is suitable for paternity analysis. Our study provides a new set of variable microsatellite loci for A. polyneuron that may be used to estimate genetic parameters such as genetic diversity, population structure, gene flow and mating system. These markers might also prove transferable for genetic analyses in related taxa.

Genetic diversity assessed in individuals of *Aspidosperma polyneuron* and *Cariniana estrellensis* as used as seed donors in an forest gene bank

Ana Lilia Alzate-Marin1, Ronal Ferreira-Ramos2, Marcela Guidugli3, Carlos Alberto Martinez2, Maocyr Antonio Mestriner1

1Departamento de Genética, FMFR, Universidade de São Paulo, Ribeirão Preto, SP, Brazil; 2Programa de Pós-Graduação em Biologia Comparada, Departamento de Biologia, FCLRP/USP, Brazil; 3Departamento de Biologia, FCLRP/USP, Brazil

E-mail: ronal@1977@yahoo.com.br

BMC Proceedings 2011, 5(Suppl 7):P8

**Background:** The neotropical tree species *Aspidosperma polyneuron* and *Cariniana estrellensis*, known as peroba-roxa and jequitibá-branco respectively, are characteristic of late secondary semideciduous Atlantic forest in submontane formation. Their wood is widely used for carpentry and construction. Increasing logging, intensive agriculture and urban expansion placed *A. polyneuron* in the Red List of Threatened Species [http://www.iucnredlist.org/apps/redlist/details/32023/0] while *C. estrellensis* is considered an endangered species. So, in situ conservation of these forest species is critical while ex situ collections as gene banks is an important complementary approach. Our study assessed and compared the genetic diversity of *A. polyneuron* and *C. estrellensis* in two stands aiming to provide subsidies for the ex situ conservation of these important genetic resources.

**Material and methods:** Leaf tissues of mature trees of two disturbed stands (SI and SII) of *A. polyneuron* and *C. estrellensis* were sampled and stored at -20°C. SI was composed by isolated individuals of an extensive area located among Pardo river and Mogi-Guaçu river basins used as seed donor of a Forest Genetic Bank, at the University of São Paulo in Ribeirão Preto campus (BG-USP/RP), SP-Brazil. SII was one of the last natural populations around Ribeirão Preto region of an isolated fragment of 7.5 ha located on Aguas Claras farm in Cravinhos Municipality (21°17'47"S; 47°40'29"W).

DNA extraction was performed according to [1]. SSR markers development for *C. estrellensis* and for *A. polyneuron* (Ferreira-Ramos, unpublished) were used for this study (Tables 1,2). Microsatellite loci were amplified individually according [3]. FSTAT software [http://www2.unil.ch/poggen/software/fstat.htm] was used to calculate the genetic parameters per locus and sample: mean number of alleles (A), the observed (H0) and expected heterozygoses (H_e), Wright’s fixation index was calculated as 1 - H_e/H_o. Deviation from Hardy-Weinberg equilibrium (HWE) was measured using GDA software [http://hydropdicytion.eeb.uconn.edu/people/plewis/software.php].

**Results and discussion:** For both species, the genetic diversity was higher in SI than SII (H_e [SI] = 0.65/0.47, H_s [SI] = 0.72/0.61) for *A. polyneuron* and *C. estrellensis*, respectively. For *A. polyneuron*, the expected heterozygosity (H_e) was higher than observed heterozygosity (H_s) in SI and SII. For *C. estrellensis* H_s was higher than H_e in SI and the opposite was found in SII. Fixation index was higher in SI than SII for both species (F_IS = 0.30/0.11, F_ST = 0.29/0.05) for *A. polyneuron* and *C. estrellensis*, respectively), suggesting inbreeding. Significant departures from HWE were observed for most loci in both species mainly in SI, which is likely due to population subdivision (Wahlund effect).

In summary, our study revealed a high diversity for the seed donor trees of *A. polyneuron* and *C. estrellensis* (SI), suggesting that this diversity was incorporated into BG-USP/RP. Indeed future progeny studies will be able to confirm these results. The low diversity found in SI for *A. polyneuron* highlights its threatened situation in this stand, on of the last natural populations in Ribeirão Preto (SP-Brazil). For *C. estrellensis*, a higher genetic diversity was observed which may be due to greater number of trees in the population, preferentially outcrossed mating system and probably gene flow from outside the fragment studied.

**References:**

dispersal distance in both conditions and an absence of reproductive isolation. They also show high pollen immigration and dispersal distance among the tree groups. The results suggest that fragmentation increases divergence in *Ararucaria angustifolia*. The population in continuous forest showed higher genetic diversity in the adult population than the population of trees in fragment. The reducing the heterozygosity were low, may be due the recent forest fragmentation history. There are more inbreeding in fragmented population than in continuous population. Fragmentation increased the genetic divergence among the fragmented population. However, the genetic results indicated the presence of long-distance dispersal leading to functional connectivity between isolated forest fragment. The survival of remnants of *Ararucaria angustifolia* patches as well as single trees in the agricultural landscape is key factors for species conservation and could be applied to environmental payment services, these strategy for *A. angustifolia* is an integration of conservation strategies across reserves and the surrounding matrix, including productive agricultural areas, to assist gene flow movement between temporarily suitable habitats.

Microsatellite variability between apricot and related *Prunus* species

Fatemeh Maghuly*, Margit Laimer
Plant Biotechnology Unit (PBU), Dept. Biotechnology, University of Natural Resources and Life Sciences, Muthsgasse 18, 1190 Vienna, Austria
E-mail: m.laimer@iam.boku.ac.at

BMC Proceedings 2011, 5(Suppl 7):P10

Background: Apricots, family Rosaceae, are economically important representatives of the genus *Prunus*. The number of apricot species ranges from three to ten, depending on the classification system adopted. The major obstacles to expansion of apricot production are irregular yields and low resistance to diseases. Compared with the high genetic variability in related species, apricots are not so variable and thus interspecific hybrids were proposed as a means to overcome deficiencies inherent in the common apricot. To estimate the extent of variation in apricot germplasm, between ecogeographical groups and related species, is very useful for planning breeding programmes, through diversity analysis, cultivar identification or marker-assisted selection.

Methods: One hundred accessions of *P. armeniaca* representing the European, Irano-Caucasian, Central Asian and North American genepool, three accessions of *P. mandshurica* and one accession each of *P. ansu*, *P. brigantaica*, the interspecific hybrid Plumcot,*P. x dacycarpa*, *P. mume*, *P. siberica* were analysed with 10 apricot SSR loci on an ABI 3100 capillary sequencer [1]. A total of 196 alleles were detected varying from 11 to 27 with an average of 16.9. Out of them, 59 alleles occurred only once (so-called private alleles). 34 (58%) private alleles were also found in related species. Non-amplified alleles were observed in four samples of the related species (*P. siberica* and *P. brigantaica*). *FST* values ranged from 0.5121 to 0.3503, with an average of 0.4459 (Table 1). It is known, that *FST* values up to 0.05 indicate negligible genetic differentiation whereas >0.25 means very great genetic differentiation within the population analyzed. In *Prunus*, high levels of genetic differentiation could be explained by the mating system. The data indicate a low gene flow (as described by *Nm*; Table 1). These results could be attributed to different geographic origins of the species or the influence of the breeding strategy.

**Results and conclusions:** Genetic similarity among common apricots and related species was quantified using Nei’s [2] genetic distance and genetic identity based on allele frequencies (data not shown). The lowest genetic identity (0.000) was found among *P. mandshurica*, *P. brigantaica*, *P. mume* and *P. dacycarpa*, and between Plumcot and *P. mume*. The highest genetic identities (0.81) were found between Western European and North American accessions and among Irano Caucasian and Eastern European groups. To demonstrate the genetic relationship between common apricots from different ecogeographic regions and related species, a neighbor joining dendrogram based on genetic distance was produced (Figure 1). The accessions are divided into two groups, one containing all common apricots and hybrids thereof, and the other containing all related species. In general, results show that the common apricots are remote from related species. The tree supports that the *P. x dacycarpa* and Plumcot, known to be a *P. armeniaca* hybrid, are intermediates between common apricot and other related species. *P. ansu* and *P. siberica* appear distant from the others accessions, and in fact they are the most distantly related species. It is interesting to know that some authors even consider *P. ansu* as a separate species [3]. In this study *P. siberica*, the species having the largest distribution area of all apricot species, and *P. mandshurica*, being present in the very cold area, cluster together. In the analyses they appear far from the common apricot species, which confirms them as being markedly different from *P. armeniaca*. Maghuly et al. [1] described that *P. x dacycarpa*, *P. brigantaica* and Plumcot were distant from the common apricot cluster. In fact, *P. brigantaica* is the most distantly related species, while *P. x dacycarpa*, a hybrid between *P. armeniaca* and *P. cerasifera*, was found intermediate between the apricot groups and Plumcot, which is a hybrid between *P. armeniaca* and *P. sibirica*.

Background: The rubber tree [Hevea brasiliensis (Willd. ex Adr. De Juss.) Muell-Arg.] is native from the Amazon region which has great economic importance for being the largest source of natural rubber in the world. Although Brazil is the center of origin and genetic diversity of this culture, the country is currently responsible for only 1% of the world production. Besides offering optimal weather conditions for crop development, the Amazon rainforest region is also favorable to the development of the fungus known as SALB (South American leaf blight), which causes the disease-off-leaves. Leaves fall sharply reducing the production of latex, limiting the production of rubber in this region. Thus breeding programs are seeking for clones which are resistant to this fungus and with high production in escape regions, which provide stress conditions such as low temperatures, high altitude, wind and other diseases [1]. The rubber tree is perennial and requires about 30 years to obtain an improved variety, starting from the controlled pollination of a clone to the final recommendation. Molecular markers such as microsatellites (Simple Sequence Repeats, SSRs) are an important tool for diversity studies and potentially to assist breeding programs. This study aimed to develop an enriched microsatellite library for H. brasiliensis, characterize these developed microsatellite markers and test the transferability of these markers to other species of the genus Hevea.

Material and methods: For this study we used 36 accesses of H. brasiliensis donated by the Agronomy Institute of Campinas and one accession of each of six other species of genus Hevea (H.nitida, H. pauciflora (2), H.camargoana, H.guianensis, H.rigidifolia andH. benthamiana) provided by Embrapa. Genomic DNA samples were extracted from lyophilized leaf tissues using a modified CTAB method [2]. Trinucleotide and dinucleotide enriched genomic libraries for H. brasiliensis were constructed. The DNA samples were digested with AFAI and enriched using (CT)8 and (GT)8 biotinylated microsatellite probes for the dinucleotide library and (ATC)8 and (CCT)8 for the trinucleotide library. The clones obtained were sequenced and the sequences were evaluated with the Microsat program, which removes parts of the vector and the adapters and verifies the presence of restriction site within the sequence. After this step, the sequences were aligned and edited using the program SeqMan (DNAStar Inc.), which also allows analyzing the redundancy of the library. The identification of microsatellites was performed using a research tool SSRs SSRT – “The Simple Sequence Repeat Identification Tool” available at Gramene [http://www.gramene.org]and primers complementary to sequences flanking the microsatellites were designed by Primer Select (DNAStar Inc.), which also allows analyzing the redundancy of the library. The maximum number of alleles per locus was 17 and eight loci were monomorphic. The PIC values ranged from 0.83 to 0.06, the observed and expected heterozygosity ranged from 0.86 to 0.06 to 0.90 and 0.06 respectively. A population analysis divided the 36 accesses into two groups. The cross-amplification of these microsatellites loci was tested in six other species of the genus Hevea. The percentage of cross-amplification in others species of Hevea ranged from 94.2% to 82.6%, with H. nitida with the highest percentage of transferability and H. camargoana with the lowest one. This high percentage indicates that the regions flanking the microsatellites are well conserved between species of Hevea. These markers will be useful to breeding and conservation studies of H. brasiliensis and related species.

This work aims to analyze the phylogeography of *Schizolobium parahyba* (Fabaceae), which includes two varieties with a disjunct distribution, from Southern Brazil to Central America. Neotropical rain forests, focus on four largest wet forests: Atlantic forest, Amazonian forests, Andean forest and Central America forest. The genetic diversity and differentiation of populations among *S. parahyba* populations using sequences of three cpDNA regions (*psbA-trnH*, *tml-trnF* and *matK*) and one nrDNA region (ITS) were analyzed. The presence of the significant phylogeographic structure was inferred by testing if G1 and N2 were significantly different and a spatial analysis of molecular variance was made with both markers. Using cpDNA (matK) sequences of the *S. parahyba* and other Fabaceae species and fossils, we estimated de divergent time for *Schizolobium* clade and using the average ITS substitution rate reported for a range of woody plants, we estimated the divergent time between the two varieties. The high levels of genetic diversity in some populations of *S. parahyba* and two centres of genetic diversity that correlate with the two known varieties: one in the southeastern Atlantic forest, and the other in the Amazonian basin. In contrast, the populations from Northeast Atlantic forest and Andean-Central America forests showed low level of genetic diversity and divergent haplotypes, probably because the founder effect after dispersion. The results suggest dispersion from southeastern Atlantic forest to Amazonian, Andean and Central America forests. We verify high level of genetic structure, with 68% (nrDNA) and 82% (cpDNA) of the total genetic diversity due to differences among populations. Twenty-one haplotypes were found with cpDNA and four with nrDNA and no haplotypes were shared between varieties. The age for *Schizolobium* clade using matK sequences was estimated ranging from 8.4-23.0 My and the divergence between two varieties using ITS sequence variation was of the 6.5 My. In conclusion, the variation pattern of cpDNA (matK) and nrDNA (biparental inheritance markers) demonstrates different insights into the phylogeographic structure and gene flow in *S. parahyba*. This comparative analysis of cpDNA and nrDNA markers can help a deeper understanding of the dynamics responsible for both ancient and more recent events that have shaped the current distribution of genetic variability in Neotropical plants. Theresults are relevant to conservation efforts and ongoing work on the genetics of population divergence and speciation in these Neotropical rainforests. Also, for the long-term conservation of the genetic diversity of *S. parahyba*, including the divergent lineages, the two varieties, it would be important to design strategies that aim to preserve most of its lineages.

### Background and objectives: Cork oak (Quercus suber L.) is one of the dominant broadleaved woody species in the western Mediterranean Basin, defining unique open woods. These woodlands have an outstanding economical and ecological value in this region, particularly in Portugal, where they sustain a strong cork industry. In the context of a prospective management of these sustainable ecosystems and renowned reservoirs of biodiversity, it is vital to better understand how the genetic variation of *Q. suber* natural populations is spatially organized so reasonable guidelines for conservation can be provided. On the other hand, knowledge of how past climate fluctuations influenced the patterns and dynamics of *Q. suber*, shaping the ranges of the species in the Mediterranean peninsulas, is of the utmost importance for our perception of what can happen in the future. Although a great deal of details on the genetic divergence of the Mediterranean cork oak populations has been uncovered and several hypotheses have been advanced concerning its evolutionary history, there is still much to unravel. For instance, Portuguese natural population sampling included so far in previous studies has been very deficient. To achieve this goal a different and complementary analysis of cork oak’s genetic diversity was initiated under a phylogeographical framework based on chloroplastial DNA sequences. This study is the starting up of a project aiming at assessing the genetic diversity and differentiation of natural cork oak populations from the entire Mediterranean distribution, with the intent of understanding patterns of biodiversity, gene flow and population admixture, as well as to infer possible evolutionary events.

### Materials and methods: We used 3-5 samples from 25 populations collected across the range of distribution of cork oak, in a total of 115 individuals. Three chloroplastial DNA (cpDNA) intergenic spacer regions (*TmF-F1*, *Tms-PsbC2* and *TmH-PsbA3*) were amplified and sequenced. Fourteen individuals of *Q. rotundifolia*, five of *Q. coccifera*, two of *Q. ilex*, and one of *Q. robur*, *Q. faginea*, *Q. pyrenaica*, *Q. situsianus*, *Q. rubra* and *Q. canariensis* were also analyzed as comparative references. *Castanea crenata* was used as outgroup. The alignment was developed in Clustal X 2.0.12 [4] and manually refined. The phylogenetic trees were made with PAUP 4.0b99 [5], using a Maximum Parsimony analysis method.

### Results: Regarding the cpDNA regions under study, two main lineages of cork oak haplotypes were found: one lineage closely related to *Quercus rotundifolia* and *Q. coccifera*, (*introgressed lineage*), mainly present in Iberia and Morocco; and a second lineage that contrastingly seems “pure”, which is the most common and does not appear to be shared with any other *Quercus* species (*pure lineage*). Three distinct sublineages are shown in the “pure” lineage, corresponding to the Eastern populations, Sicily and the Western populations, although separated by minor differences. Some populations present cpDNA haplotypes belonging to both lineages, while others are specific for one of them. An absence of introgression in the eastemmost populations of cork oak seems also apparent.

### Conclusions: Although these preliminary results seem to confirm previous ones, some major differences are suggested, such as too few differences between the western and eastern groups to be explained by a Tertiary divergence pattern, as previously suggested [6], but rather more consistent with a more recent expansion from few refugia; and widespread and multiple introgression events from *Q. rotundifolia* and *Q. coccifera*, common in peripheral western populations.

Background: Salix koreensis native to Korea, Japan, and China, is a deciduous broadleaved tall tree growing throughout Korea. This species is dioecious and planted along the streets and for landscaping. Along the rivers the species grows well reaching up to 20 meters in height. Trees bloom in April and fruits ripe in May. This study was carried out to investigate the genetic diversity of S. koreensis within and among 10 populations throughout South Korea using ISSR marker analysis.

Materials and methods: From 10 populations identified throughout the country 8 to 11 individual trees per population were sampled, totalling 84 individual trees. Twigs with leaves were collected and used as material for genetic analysis. DNA extraction was performed using GENE ALL plant DNA purification Kit (Geneall, Korea) and amplified by PCR using 5 UBC (University of British Columbia) primers (#807, #834, #842, #856, #881) which showed good results in previous experiments. PCR products were electrophoresed and gels photographed. Amplified fragments were visually scored as present (1) or absent (0). Observed and effective numbers of alleles, Shannon’s information index, number of polymorphic loci, Nei’s genetic distance were estimated using POPGENE 3. and genetic distance was analysed using UPGMA.

Results and conclusions: The overall number of polymorphic ISSR amplicons was 80 and mean per primer was 16. The percentage of polymorphic loci was as follows: Namwon population had the highest level (61.25%), Seomjin river population had the lowest level (37.50%) and the overall mean was 48%. Shannon’s Information Index indicating genetic diversity ranged from 0.17 (Seomjin river population) to 0.28 (Hanam population) with a mean of 0.24. Shannon’s information index of this species was lower than the one found in other species. This result is likely due to the fact that S. koreensis is frequently propagated by asexual reproduction. The UPGMA dendrogram based on Nei’s genetic distance did not show any clear geographic pattern. The Seomjin river population with low genetic diversity was genetically more distant from the other populations and the Upo population was the next more distant one. Hanam and Yangchon populations were the ones more genetically related.

Development and characterization of microsatellite loci in Grevillea robusta
Camila Mantello1, Davi R. Cerqueira2, Valderês Aparecida Sousa2, Andana Virginia Aguiar1, Anete Pereira Souza1
1UNICAMP, Brazil; 2Embrapa Florestas, Brazil
E-mail: drigoni@cpnp.embrapa.br

Background: Grevillea robusta is a native tree to the subtropical coastal regions of northern New South Wales and southern Queensland in Australia. In Brazil, Embrapa Forestry and its partners have established many provenance/progeny tests to increase the species genetic basis and aim to implement a breeding program to improve timber production. Genetic variability of these tests has been monitored through the assessment of quantitative traits. However, the genetic evaluation of materials based on phenotypic traits is influenced by many environmental factors. Estimates of some genetic parameters such as gene flow and
parentage are possible using molecular tools as most common molecular marker, microsatellite (Simple Sequence Repeats, SSRs) which are codominant and highly polymorphic. Genetic markers have intensively applied for the main strategies in breeding programs, especially when economically important traits are difficult measure because of low heritability. The aim of this study was develop microsatellite markers for Grevillea robusta through enriched library in order to estimate the genetic diversity and structure of the species, and direct efforts for the conservation and management of its active germplasm banks.

Methods: The genomic-enriched library was constructed following the protocol described by [1]. The genomic DNA was digested with AFAI and enriched in (CT)8 and (GT)8 repeats. Enriched fragments were amplified by polymerase chain reaction (PCR), connected to a pGEM T-easy vector and transformed into competent XL1- blue Escherichia coli cells. The positive clones were selected using the B-galactosidase gene and then grown overnight in an HM/F medium with ampicillin. After PCR, 95 positive clones were sequenced in both directions using the T7 and SP6 primers as well as the Big Dye terminator Kit. The sequences were assembled and edited in Seqman (DNAStar) and the repetitive regions were found using the Simple Sequence Repeat Identification Tool [2]. Primer Select (DNAStar) and Primer 3 plus were softwares used to design primer pairs flanking the microsatellite regions.

Results and conclusions: Of the ninety five sequences cloned, seven contained microsatellite sequences. Only five of them showed repeats and adequate flanking regions for primer design. The observed proportion of trinucleotide was 4.21% (4), while tetranucleotide and pentanucleotide were 2.11% (2) and 1.05% (1), respectively. Of the total of nucleotides found 100% are simply perfect. The explanation for this low yield sequences (7.4%) can be attributed to the genomic-enriched procedure. These sequences will be validated and promptly used to estimate the genetic diversity, gene flow and parentage of the Brazilian germplasm collections.

E-mail: fabiano.salgueiro@gmail.com
BMC Proceedings 2011, 5(Suppl 7)P17

Background: Past climate changes have severely influenced the current distribution of species and their genetic diversity. Phylogeography is the study of the principles and processes governing the geographic

Figure 1(abstract P17) Map showing the geographic distribution of the cpDNA haplotypes in the Calophyllum Braziliense populations.
distributions of genealogical lineages [1]. South America has the world's largest area of swamps, floodplains and wetlands in general [2]. Brazil's major wetlands cover 2% of the country's huge territory [3]. However, from a plant ecology standpoint, Brazilian freshwater wetlands are largely unknown and the scarce data available refer mostly to flooded forests of the Amazon [4]. Calophyllum Braziliense Camb. (Calophyllaceae), also known as guandani, jacareúba or landim, is a canopy tree species typical of waterlogged areas from South and Central America. This species occurs in the humid tropical forests of Central America, Amazon Forests, Atlantic Forest (including restingas); and in the riverines forests of the Cerrado biome (brazilian savannah) [5-6]. However, unlike other species typical of flooded areas, C. Braziliense shows none of the morphological features common to flood-adapted plants. Calophyllum Braziliense is a hermaphroditic tree pollinated by bees. Its seeds are animal (mainly by bats) or water dispersed. The timber has excellent characteristics and is widely used. Calophyllum Braziliense is also used in vegetation restoration programs and its leaves extract presents anti-inflammatory activity [7]. This study examines the phylogeographic patterns of C. Braziliense based on the cpDNA intergenic region psbA-trnH.

Methods: Twenty-four populations of C. Braziliense were sampled from Costa Rica (10° 12′ N, 83° 47′ W) to the Paraná State in Brazil (25° 34′, 48° 27′ W). Samples were collected from about 5-10 adult trees in each population, totaling 192 individuals. The cpDNA was extracted from leaves or cambium using the CTAB procedure described by Doyle & Doyle [8]. After a screening for cpDNA amplification and polymorphism in C. Braziliense, the psbA-trnH intergenic regions was selected [9]. Sequences were aligned using CLUSTAL-W implemented in the MEGA 4 software. The cpDNA haplotypes were defined by analyzing the sequences with DNASP 4.0.1. The genetic diversity indexes were estimated in ARLEQUIN 3.01. The phylogenetic relationships among the haplotypes were estimated using the median-joining algorithm implemented in NETWORK 4.1. An analysis of molecular variance (AMOVA) was performed in ARLEQUIN. A spatial analysis of molecular variance (SAMOVA) was conducted using the SAMOVA 1.0 software. To evaluate the hypothesis of population expansion, neutrality tests were computed in DNASP and ARLEQUIN.

Results: A total of 263 aligned positions were obtained for the psbA-trnH locus. Twenty-eight variable characters were analyzed resulting in seven cpDNA haplotypes (Figure 1). The haplotype diversity (h) for each population ranged from 0.0 to 0.533 and the nucleotide diversity (θ) from 0.00 to 0.01882. Similar levels of genetic diversity were observed for other tropical species [10,11]. Most of the Atlantic rain forest populations (13/14) are monomorphic and present the same haplotype (H1). Generally, the remaining populations present different private haplotypes. Spatial analysis of molecular variance (SAMOVA) identified seven phylogenetic groups (k=7, Fct = 0.926), one consisting of 13 monomorphic populations from the Brazilian Atlantic rain forest and more three populations from the Cerrado biome. Most of the other populations constitute different phylogenetic groups. Neutrality tests suggest expansion for the Atlantic rain forest populations. The AMOVA analysis reveals that most of the variation was found between populations (0.8788, p<0.00005). A great genetic distance was observed between Central America (Costa Rica) and the others populations, even from the Brazilian Atlantic rain forest. Similar results were observed when Swietenia macrophylla (mahogany) populations from Central and South America were compared [10].

Conclusions: The genetic data obtained here for C. Braziliense based on chloroplast DNA diversity indicate a recent expansion for the Atlantic rain forest populations. Our results suggest that the Northeast of Brazil maintained large populations during the last glacial period and that the Southeast and South populations may have undergone a pronounced retraction process, followed by a recolonization process with a strong founder effect. Thus, the recolonization of the South and Southeast region of the Atlantic rain forest probably occurred from these more stable areas in the Northeast.

and divergence among natural populations were analyzed using $F_{ST}$ statistics. A simulated annealing algorithm, implemented in the software SITES [3] was used to establish the minimum number of local populations necessary to complement the germplasm bank so that all alleles (expressed as present or absent in each local population) are represented at least once (i.e., representation goal). The search was performed using two hundred runs and 10,000,000 iterations for each run. The problem is analogous to the ecological problem of finding a minimum number of new conservation priority areas that represent all species, after fixing a few already established natural reserves (see [4]). However, there may be frequently multiple combinations of local populations that satisfy the representation goal, so the first 100 solutions of SITES were also retained. The relative frequency of each local population in the alternative optimized solutions is an estimate of the “irreplaceability”, or relative importance, of the populations to the overall goal of representing the entire genetic variability (alleles).

Results and discussion: The genetic variability of D. alata for the microsatellite loci analyzed here was low compared with other forest species in the same region (e.g., [5]). Out of the 9 loci, on average 78% were polymorphic within natural populations, and 67% were polymorphic in the germplasm bank. The mean number of alleles per loci were 2.7 and 4.4 for the natural populations and for the germplasm bank, respectively. The He and Ho were equal to 0.36 and 0.30 for natural populations, and 0.36 and 0.23 for the germplasm bank. The $F_{ST}$ was significant and equal to 0.259, indicating a relatively high differentiation among the local populations. The simulated annealing revealed that only 4 local populations, located in Mato Grosso and Mato Grosso do Sul (Figure 1; 1-CMT, 5-AMS, 19-RAMT e 25-CAMT), are necessary to represent all alleles that appeared in the species, complementing in an optimum way the genetic variability already present in the germplasm bank. The solution is unique so that all these 4 local populations have 100% of irreplaceability.

Our analyses confirm that the germplasm bank currently established in the Universidade Federal do Rio Grande do Sul preserves the genetic variability of a relatively large proportion of species’ range in the Cerrado biome. To improve such representation it is important, however, to sample more local populations in the west portion of the species’ distribution, in Mato Grosso region. It is important to note that these populations possess unique alleles that are not found elsewhere, so they are irreplaceable for achieving the conservation goal. If these populations are lost (i.e., extinct), there will be genetic erosion reducing total genetic variability in this species. So, an effort to sample and grow up individuals or progenies from the 4 populations, preferentially coupled with in situ conservation programs in these natural populations from Mato Grosso region, must be urgently done. Our optimization analyses reveals that only a few samples are necessary to achieve a more complete representation for the species, and this is important to reduce sampling and maintenance costs without losing efficiency in terms of establishing conservation and future breeding programs for the species.

BMC Proceedings 2011, 5(Suppl 7):P19

Introduction and objectives: The Atlantic Forest (AF) is considered the second largest tropical forest in South America with high species richness and endemisms, harboring a large diversity of animals, plants and habitats types [1]. This biome covers an area of more than one million square kilometres along the Brazilian coast and extending to eastern Paraguay and northeastern Argentina [2]. AF is considered one of the

Figure 1(abstract P18) Natural populations (red arrows) of D. alata that must be sampled to achieve the conservation goal of representing all alleles from 9 microsatellite loci complementing, in an optimum way, the genetic variability found in the germplasm bank reared at “Escola de Agronomia, Universidade Federal de Goiás”.
most threatened ecosystems on Earth due to intense disturbance, having been reduced to only 7.5% of its original area [1]. Despite an increase in research efforts in the past few years, studies of AF species diversification and knowledge about its evolutionary history is still scarce. Vegetation changes in the Atlantic Forest related to climatic changes during the Pleistocene have been registered in paleoecological studies, with the replacement of large areas of forests by subtropical grasslands and savannas during cooler and drier conditions [3,4]. Also, studies of paleoclimatic models, predicted the presence of historically stable areas (refugia) in the Atlantic Forest during the Late Quaternary [5]. *Eugenia uniflora* L. (Myrtaceae), a shrubby tree with edible cherry-like fruits which is locally known as tangera or Brazilian cherry. This species is one of the key species in the Atlantic rain forest geomorphological domain, which includes the Atlantic forest and the adjacent Restinga ecosystem [6]. *E. uniflora* occurs in areas of medium and large levels of rainfall and can also be found in different vegetation types and ecosystems. This species present economic and folk medicinal applications and is an important pioneer species in the Restinga ecosystem and has been used to recover and manage disturbed and fragmented areas. Our aim in this study was to investigate the phylogeny and genetic diversity of *Eugenia uniflora* to help elucidate the evolutionary history of this species as a model for gain insights into past vegetation patterns in the Brazilian Atlantic Forest.

**Methods:** Forty-six populations of *E. uniflora* were sampled across the Brazilian Atlantic forest. The samples were collected as leaf material (silica gel dried) from natural populations. Total genomic DNA was isolated using the CTAB method [7]. Two cpDNA regions (psbA-trnH and trnC-ycf6) were used for population analysis based on sequence quality and degree of variation. These regions were amplified using universal primers. The individual consensus sequences were aligned through CLUSTALW [8] implemented in MEGA4 [9], then carefully improved manually. The genealogical relationships among haplotypes were estimated by using the median-joining method implemented in Network 4.2.0.1 (Fluxus Technology Ltd. at http://www.Fluxus-engineering.com). Molecular diversity estimates were calculated using Arlequin 3.1(T) and DNAsp 5.0 [10]. Genetic structure was further examined by the analysis of molecular variance (AMOVA), as implemented in Arlequin version 3.1.

**Results and conclusions:** The total combined cpDNA matrix presented 1224 sites, which eight were variable. Eight haplotypes were found and the haplotype diversity (h) ranged from 0 to 0.733 and the nucleotide diversity (θ) from 0 to 0.00140. Total haplotype and nucleotide diversities were 0.433 and 0.00088, respectively. The highest haplotype diversity was found in populations ITAP, PALM, CAPI and GRAV from the Atlantic forest South. Populations from Northeast were monomorphic. The most common haplotype was H1, present in 39 of 46 populations. The AMOVA analysis showed a very strong differentiation among all *E. uniflora* populations (ΦCT = 0.771, P<0.0001). These results can help a deeper understanding of the dynamics responsible for both ancient and more recent events that have shaped the current distribution of genetic variability in Atlantic Forest and also have implications for conservation efforts. For the long-term conservation of the genetic diversity of *E. uniflora*, it would be important to design strategies that aim to preserve most of its lineages. For such, the South region is a key piece, as it houses many divergent and endemic haplotypes.

mixed equimolarly to obtain a composite cDNA library for each population and developmental stage. The libraries were sequenced on a Roche 454 FLX to produce 495,915 reads in total. After cleaning and removal of duplicated reads, reads were mapped onto oak unigenes [2]. A digital gene expression analysis was performed using both r statistics [3] and R BioConductor packages (edgeR, DESeq and goseq). Homology searches were carried out by Blastx against SWISS-PROT and TAIR9 databases with e-value cutoff of 1e-5. Gene ontology (GO) annotations were based on the top blast hit against SWISS-PROT database. To validate bioinformatic analysis, Q-PCR was performed for 13 selected genes. One microgram of total RNA was reverse transcribed using ImProm-II™ reverse transcription system (Promega) according to the manufacturer’s instructions. Q-PCR reaction and quantification were performed on a Chromo4 Multicolor Real-Time PCR Detection System (Bio-Rad).

Results and conclusions: We identified 48 common contigs that showed differential expression by three bioinformatic programs (R statistics, edgeR and DESeq) and selected 13 genes for Q-PCR analysis with the main goal to validate the result obtained in silico. One gene (cold shock protein) showed multi-banding pattern and discarded from the analysis. Among the 12 remaining genes, only one gene (cold shock protein) showed contradictory expression pattern between in silico and Q-PCR analysis. The high success rate of Q-PCR analysis (11/13 = 84.6%) indicated that the verified genes are likely to represent endo- and ecodormancy stages. Two genes (Globalin and XET) were confirmed as up-regulated in endodormancy, while nine genes (GASA, GST, DRM1, XERO2, PIP, AWPM, GID, LEA and ELP) were found to be down-regulated in ecodormancy. Analysis in terms of GO showed genes responsible to abiotic and endogenous stimuli as well as stress related were enriched in the set of 48 genes. Similar trend was observed in expression analysis for raspberry bud dormancy, where high percentage of stress-response/defense/detoxification-related genes were identified [4]. In grape also, most of genes expressed in buds at the end of dormancy were attributed to the oxidative processes and stress responses [5]. Although the number of genes identified is small and further verification through time course change in their expression will be needed, these candidates will serve as stepping stone to dissect the molecular mechanisms involved in bud dormancy in forest trees.

BMC Proceedings 2011, 5(Suppl 7):P21

Background: The forest fragments of Stryphnodendron adstringens have disappeared because of the high rate of Brazilian Savannah deforestation for commercial purposes, such as eucalypt, citrus, soybean, and sugar cane crops that have been intensely cultivated on those areas [1]. Economically, S. adstringens is important for manufacture industries of paints and tanneries, but also is utilized for therapy against ulcers, scarsy, and for antiseptic and healing purposes [2]. Considering the forestry sector, the species is potential for building uses because of their wood have high density and durability [3]. Aiming for germplasm preservation and for breeding programs we studied the spatial genetic structure of S. adstringens based on SSR markers.

Methods: Juvenile leaves of 38 individuals of S. adstringens were collected in natural population, of approximately 200 individuals, in Botucatu State Forest belonging to Forestry Institute, São Paulo State, Brazil. The population is located from 22° 55’ 55” S to 22° 56’ 39” latitude and from 48° 27’ 19” W to 48° 27’ 33” W longitude, through 860 m altitude, totaling 33 hectares of Savannah. The lab procedure protocol based on Ferreira and Grattapaglia [4], and adapted to S. adstringens, for DNA extraction was used. We assessed the transferability of 98 primer pairs developed for different tree species of several families and genera. The amplification was performed at 92°C for 2 minutes by initial denaturation, 45 cycles of 1 minute at 92°C, 1 minute at annealing temperature, and 1 min at 72°C, and ending to 10 minutes at 72°C. The analysis of spatial autocorrelation of sampled population, with local coordinates, and variable alleles of individuals was estimated. The ‘Spatial Genetic Software (SGS) Version 1.0 program for distance classes per each allele, and considering 1000 bootstraps to get the Moran’s I Index [5] were used. The expression was:

Where:
I = Moran’s I index, which can take values between -1.0 (negative autocorrelation) and + 1.0 (positive autocorrelation);

The table shows the correlation of S. adstringens indicating that the distances, among individuals of Botucatu State Forest, from 0 to 33 and from 99 to 132 meters have significant spatial autocorrelation.

Table 1 Correlogram using Moran’s Index (D) with confidence interval (CI), probability of exclusion (P), number of comparisons (CN), and value indicating absence of spatial autocorrelation D = -0.0270 for Stryphnodendron adstringens

presented spatial structure. According to Sebbenn [6] is common in tropical species, similarities until 100 meters; therefore to collect high variability of S. adstringens it is important to obeyed distance up to 132 meters.

Conclusions: Significant results were observed for the class distances from 0 to 33 meters and 99 to 132 meters, showing there is spatial autocorrelation for S. adstringens.

BMC Proceedings 2011, 5(Suppl 7):P22

Background: Pinus (Pinaceae) is the largest existing genus of conifers, with over 100 widely recognized species. Pines are an important source of wood, paper and resins, among others. Genetic improvement of Pinus species is a challenging endeavor. Breeding cycles typically last for decades, significant changes take place in wood properties and growth patterns with the transition from the juvenile to the adult phase and most traits are multi-factorial with low heritability [1]. Genomic Selection (GS) could radically reduce the time required for completion of a cycle of genetic improvement by precluding the progeny testing phase, significantly increasing the selection efficiency relative to conventional breeding [2,3]. To put GS into practice, genome-wide, high-throughput and cost-efficientmarker are needed to advance this genomics assisted breeding approach focusing purely on prediction of performance, precluding gene-trait association discovery. To this end we are developing a high-throughput DNA genotyping platform for Pinus taeda based on the genome complexity reduction DArT (Diversity Arrays Technology) technology that has been successfully developed for many plant species including some with very large and complex genomes such as wheat [4] and sugarcane [5].

Methods: For DArT array probe development population samples of 16 species of Pinus, 24 provenances of Pinus taeda L. and two mapping populations were used as starting material organized in pooled samples. For microsatellite and DArT mapping a selected set of 65 microsatellites. Genotyping was performed in an ABI PRISM 3100XL using 4-color fluorescent detection in multiplexed sets of 2 co-amplified microsatellites. Linkage analyses and map construction was carried out using JOINMAP 3.0.

Results: A total of 856 and 930 markers were found polymorphic across samples of 24 individuals of each one of two mapping populations, while 1,776 DArT markers were polymorphic in a panel of 16 species, two individuals per species and 16 Pinus taeda US provenances, one individual per provenance. A significant number of probes could not be adequately scored due to background signal resulting from the presence of highly repetitive DNA that the PstI/BstNI complexity reduction could not remove from the 23 pg Pinus taeda genome. Cot-1 DNA, i.e. genome DNA highly enriched for repetitive elements was therefore isolated from P. taeda DNA by shearing genomic DNA in autoclave, followed by DNA denaturing and re-annealing and S1 nuclease treatment. Using the Cot-1-DNA to quench repetitive probes, the recovery of assayable DArT markers was increased by 40%. When mapping microsatellites extensive locus duplication of the 65 microsatellite primer pairs resulted in a total of 182 individually “loci” scored for presence/absence in the haploid gametes. Based on the map position 96 of these “loci” actually corresponded to 48 effective loci and the other 86 are actual individual loci totaling 134. From the 134 segregating loci 110 were confidently mapped in the 12 expected linkage groups leaving two unlinked groups of 5 and 3 markers. Locus order was essentially the same for the 50 loci derived from 31 microsatellites in common with those recently mapped [7]. Interestingly, microsatellite Ptx13021 amplified 17 individually scored “loci”. Eight were allelic pairs and were consolidated in four loci while the remaining 9 were unique. Additional duplicated were seen for 15 microsatellites in different linkage groups suggesting paralogous loci.

Conclusion: In spite of the complex and repetitive nature of the Pinus taeda genome several hundred DArT markers could be confidently genotyped indicating that DArT is a robust technology to be used for conifers. A new round of DArT probe picking and marker screening coupled to Cot-1 DNA use is now underway and should provide the target number of 7,680 selected probes for an operational array. The haploid mapping population will be genotyped with this array to provide information on distribution of the DArT markers in terms of recombination fraction and genome coverage relative to the framework of microsatellites. Additionally, probes detecting mapped markers will be sequenced to eventually aid the assembly of the 7-56 genome sequence.

Effect of population structure and kinship relationships on the results of association mapping tests of growth and wood quality traits in four Eucalyptus populations

Eduardo Pablo Cappa 1*, Maria C Martinez 2, Martin N García 2, Pamela V Villabá 3, Susana N Marucci Poi 2

1 Instituto Nacional de Tecnología Agropecuaria. Instituto de Recursos Biológicos. Hurlingham, Buenos Aires, Argentina; 2 Instituto Nacional de Tecnología Agropecuaria. Instituto de Biotecnología. Hurlingham, Buenos Aires, Argentina

E-mail: ecappa@cinia.inta.gov.ar

Background: In recent years, association mapping studies have been reported for the presence of growth and wood quality traits in Eucalyptus (e.g. [1]). One problem with association studies is that they can be sensitive to the presence of population structure. The presence of population structure may generate spurious associations between markers and traits and leading to an elevated false-positive rate (e.g. [2]). Statistical approaches that account for population structure include model-based clustering [3], principal component analysis, genomic control and linear mixed model approach [4]. The mixed model of Yu et al. (2006) accounts for both major population structure, assigning individuals to subpopulations (the Q matrix), and the relatedness among individuals within and between subpopulations (the kinship (K) matrix). The mixed model approach generally performs best [2,4].

As part of the biotech MERCOSUR project (Marucci Poi et al. this volume) molecular and phenotypic data from four Eucalyptus populations have been obtained: three open pollinated (OP, half-sib) progeny trials of Eucalyptus grandis from Argentina (EgrAr) and Eucalyptus globulus from Uruguay (EgUy) and Argentina (EgAr) and one clonal trial of Eucalyptus grandis from Paraguay (EgpAr). These populations differ in the underlying substructure and genetic relatedness among individuals. It is thus important to investigate the effects of population structure and kinship on the results of associations between markers and growth and wood quality traits from these Eucalyptus populations.

Material and methods: A total of 612 trees were sampled from the EgrAr (188), EgpAr (121), EgAr (134) and EgUy (169) populations. The numbers of OP families sampled in each OP progeny trial was 132 (EgrAr), 129 (EgAr) and 70 (EgUy) from different native stand sites in Australia (from 8 to 13) and land races (from 1 to 3). The number of trees per OP family varied from 1 to 3 (EgrAr), 1 to 8 (EgpAr) and 1 to 2 (EgAr). One growth trait (diameter at breast height, DBH) and three quality wood traits (extractives in ethanol, Klasson lignin and syringylguaiacyl ratio (S/G ratio)) were studied.

All the 612 trees were genotyped using Diversity Arrays Technology (DArT) molecular markers [5]. A subset of 2816 (EgrAr), 2693 (EgpAr), 2373 (EgAr) and 2300 (EgUy) DArT markers were used in the analysis after markers with frequency greater than 0.95 or less than 0.05 were excluded.

The association mapping tests were carried out at the DArTs level using two-steps. First, for the three OP trials, the overall mean and design effects or first order autoregressive residuals for rows and columns, were fitted to deal with environmental variation. Additionally, for the clonal trial, the best linear unbiased predictions (BLUP) of clonal values were predicted. Second, the markers effects were tested on the adjusted phenotypes (OP trials) or clonal BLUP values (clonal trial) using four models [4]: 1) Simple model, in which Q and K matrices are ignored; 2) Q model, considers only Q matrix; 3) K model, considers only K matrix; and 4) Q+K model, considers both Q and K matrices. Except for the EgAr population, the Q matrix was calculated by the software STRUCTURE [3] on basis of 400 random DArT markers. The K matrix was calculated on basis of 800 random DArT markers using the software package SPAGeDi [6].

For each of the four populations, all the association tests were carried out using TASSEL software [http://www.maizegenetics.net/].

Results: All populations showed an optimum cluster number of 4. In general, for the three OP populations the compositions of the clusters coincided with the geographical native stand sites in Australia. More than 52% of the pair-wise kinship estimates were equal to 0, whereas about the 46% of the values were less than 0.25. Without taking into account the population structure and kinship (Simple model), from 0.9 to 8.5% of the DArT markers tested were associated with the growth and wood quality traits at P < 0.01. These preliminary results show a high number of associated markers that might suggest that several of them are likely to be false-positives due to population structure and/or kinship relationships among trees within each population. For all populations and most traits under consideration, the controlling only for population structure (Q model) reduced the number of significant DArTs (from 0.5 to 2.6%). This effect was more pronounced for the two OP Eucalyptus globulus populations. However, when the relative kinship coefficients between every pair of individuals were considered (K model), a more stringent reduction with respect to the Q model was observed (from 0.3 to 1.3%). This finding suggests that, when more complex interrelationship among individuals within and between subpopulations exists, the fitting Q model was not enough to reduce the number of spurious associations. It is no clear, across populations and traits, that the Q matrix should be added to the kinship effect. The reduction of number of significant DArT markers, excluding pedigree information (K matrix) in the model, appeared to be trait dependent.

Conclusions: Both population structure and kinship relatedness between individuals had effect on the association mapping tests. The kinship had a more stringent effect on the marker-traits associations. Effect on association tests depends on the populations and traits studied.

E-mail: silviabio@yahoo.com.br

Background: Rubber tree [Hevea brasiliensis (Will. ex Adr. de Juss.] Muell-Arg.), a native species of the Amazon Rainforest in South America, belonging to the Euphorbiaceae family, is world’s major source of natural latex. Brazil, despite being the center of origin and diversity of the species and latex main producer at the end of XIX century, nowadays imports around 70% of the rubber consumed in the country. Although the Amazonian basin provides optimal conditions for rubber plantation, the occurrence of South American leaf blight (SABL) disease, caused by the ascocryme Microcyclus ulei, limits the rubber production in
this region. Therefore, rubber plantation has been extended to sub-optimal areas that are prominently located in northeast India, Vietnam, southern China and southern plateau of Brazil. Besides the new conditions for crop development, these new areas present stress conditions like low temperatures, dry periods and wind. It was shown that low temperatures affect the development and latex production of rubber trees. Breeding programs have been searching for clones adapted to these suboptimal areas. A complete cycle of breeding and selection takes at least 20 years to succeed in obtaining a superior clone. As such, development of new methods for early evaluation is essential to reduce and optimize the breeding management. Aiming to help in the development of these methods, in this work, we have constructed a leaf cDNA library to study ESTs (Expressed Sequence Tags) from cold stressed rubber trees. The originated sequences from this library can be used to create an ESTs databank and will provide genetic knowledge about how rubber trees cope with chilling stress, and early evaluation would be possible in young rubber tree clones.

**Methods:** The young *Hevea Brasiliensis* Muell. Arg. clones GT1, JAN873, PR255 and PB217 were obtained from Agronomic Institute of Campinas (IAC). GT1, PR255 and PB217 clones are genitors of mapping populations of ongoing projects at Molecular Genetics and Analysis Laboratory and JAN873 clone showed chilling tolerance in field. The 24h cold treatment was performed in a diurnal growth chamber (8°C, 12h photoperiod). The collected leaves were previously wrapped up in tinfoil to prevent transcript redundancy. Leaves were sampled in intervals of 6h, 10h and 24h and total RNA was extracted by LiCl precipitation. Total RNA extracted from clones were pooled in equal amounts, according to time of sampling. The In-fusion SMARTer cDNA Library Construction Kit (Clontech) was used to construct the cDNA library. A sequenced plaque (96 clones) of each sub-library (6h, 10h and 24h) was chosen for a preliminary analysis of the library. Sequences were analyzed and clustered by the DNAStar package (DNAStar, Inc.) and Blast2Go software (http://www.blast2go.org) was used to annotate the contigs and singlets. The resulting ESTs were screened for microsatellite regions using Simple Sequence Repeat Identification Tool (SSRIT) (http://www.gramene.org/db/markers/ssrtool).

**Results and discussion:** The cold stressed leaf cDNA library has around 6,000 clones and is sub-divided into three libraries: “cold-6h”, “cold-10h” and “cold-24h”, having 2,000 clones each. The average fragment lengths from these libraries are 780bp, 625bp and 930bp, respectively. In order to perform a preliminary analysis of the libraries expression profiles, 96 sequenced clones from each library were chosen randomly. Among the 288 sequences analyzed, 87 were discarded due to sequencing reaction failure or sequencing slippage. Clustering of the remaining 201 sequences generated eight contigs and 180 singlets. All contigs and singlets were annotated and distributed into functional categories. “Hypothetical and Unknown Proteins” was the major functional category, containing 52 sequences (26%). Most of these sequences (25) belong to “cold-24h” library. Second larger functional category was “Metabolic Processes”, constituted by 34 sequences (17%). It was also in that category that libraries showed a visible difference among them: while about 20% of the sequences of libraries “cold-6h” and “cold-10h” is involved in cellular metabolic processes, in the “cold-24h” library this number falls to 13%. Chilling stress mainly causes alterations in metabolic processes and decrease in enzymatic activities. An exposure of 24 hours to low temperatures seems to be enough to trigger such a change in stressed rubber trees, which maybe could explain the higher number of hypothetical proteins in that library; however analysis of more sequences is necessary to confirm the results. Sequences that presented no similarity to any sequence in GenBank database were grouped in the “No Match”
category, which is third in number of sequences (22; 11%). These sequences may be specific to *Hevea Braziliensis* and several presented at least one ORF that could be translated. The relative distribution of all annotated ESTs into functional categories can be seen in figure 1. The presence of microsatellite regions in the sequences was also verified and 30 ESTs sequences bearing SSR regions (15%) were found: 13 dinucleotide (43%), 9 trinucleotide (30%) and 8 tetrancleotide motifs (27%). Microsatellite regions were present mostly in hypothetical protein sequences (13; 43%) and all of them were in the UTR regions. Primers for these sequences are being designed in order to evaluate their polymorphism. The sequencing process of the cold stressed leaf cDNA library is ongoing. The comparison of a small number of sequences showed a difference in expression pattern between the sub-libraries that may be confirmed by a wide analysis of their sequences. A preliminary analysis for microsatellite regions suggested that around 15% of the sequences may have potential polymorphic SSR markers. Moreover the ESTs generated will be a rich source for polymorphic SNPs markers. SNP and SSR molecular markers will be developed from these data and will be used in *H. Braziliensis* genetic mapping. These markers could provide tools for early evaluation of cold tolerant rubber tree clones, among other genetic studies.

**Background:** Sex determination in poplars is still an open question. In *P. trichocarpa*, a genetic linkage map was constructed with JoinMap v3.0 [5]. Linkage parameters were set as 10 minimum LOD and 0.4 maximum recombination fractions. Sex determination in *Populus* species is controlled by sex chromosomes, making use of linkage analysis to study sex determination difficult. The presence of common previously mapped SSR markers in several genetic studies.

**Results and discussion:** In this intraspecific *E. grandis* population, 78% of the SSR markers tested could be mapped. Most mapped SSR loci were fully informative, segregating in approximate ratios of 1:1;1:1 (either heterozygous in both parents and alleles in total). Seven SSR loci that followed approximate segregation ratios of 1:1 (heterozygous in one parent) were EMRA 47,51,101,179,676,1244,2010. From the DA'T Microarray of 7,860 clones, 31% of the marker were selected because of their high call rate (>0.80) and polymorphism between parents. A large proportion (1,503/2,381=63%) of the DA'T markers displayed a Mendelian behavior indicating that they sample single copy regions and provide markers that can be used for genetic analyses (65% segregating in 1:1 ratio and 35% in 3:1 ratio). The map was assembled with 1032 markers, including 976 DA'T, 43 SSR loci (2:6 per linkage group), seven EST-SSR and 37 EST-SSR markers; these last two classes of markers derive from a broad study (for details see Acuña et al., this journal). Capillary electrophoresis and fluorescent detection was carried out on an ABI 3130x Genetic Analyzer. A DA'T Microarray of 7,860 clones was screened for useful polymorphic markers.

**Linkage and bioinformatic analysis:** All loci were tested for goodness of fit to expected Mendelian segregation ratios using Chi-square goodness of fit tests. The assignment of DA'T sequence function was performed using the Blast2GO software [http://www.blast2go.org/]. A consensus genetic linkage map was constructed with JoinMap v3.0 [5]. Linkage parameters were set as 10 minimum LOD and 0.4 maximum recombination fractions.

**Results and discussion:** In this intraspecific *E. grandis* population, 78% of the SSR markers tested could be mapped. Most mapped SSR loci were fully informative, segregating in approximate ratios of 1:1;1:1 (either heterozygous in both parents and alleles in total). Seven SSR loci that followed approximate segregation ratios of 1:1 (heterozygous in one parent) were EMRA 47,51,101,179,676,1244,2010. From the DA'T Microarray of 7,860 clones, 31% of the marker were selected because of their high call rate (>0.80) and polymorphism between parents. A large proportion (1,503/2,381=63%) of the DA'T markers displayed a Mendelian behavior indicating that they sample single copy regions and provide markers that can be used for genetic analyses (65% segregating in 1:1 ratio and 35% in 3:1 ratio). The map was assembled with 1032 markers, including 976 DA'T, 43 SSR loci (2:6 per linkage group), seven EST-SSR and 37 EST-SSR markers; these last two classes of markers derive from a broad study (for details see Acuña et al., this journal). Capillary electrophoresis and fluorescent detection was carried out on an ABI 3130x Genetic Analyzer. A DA'T Microarray of 7,860 clones was screened for useful polymorphic markers.
Conclusions: In this work, 13 new functional SSR and 976 DArT (296 with assigned functions) markers are mapped in an intraspecific E. grandis F1 population. This map will be used to locate QTL for wood quality and growth traits in the specie. Also, this map can help to identify candidate genes and regions in the Eucalyptus genome useful for fine scale analysis with association studies that are being developed by our group (see Cappa et al., this volume). The putative functional approach combined with the genetic linkage mapping provides an advantage tool for future analysis in locating genes of interest in Eucalyptus.

Leaf blight and defoliation caused by Cylindrocladium pteridis is one of the main leaf diseases found in Brazilian eucalypt plantations in warm and high rainfall regions. The inter and intraspecific variability in the intensity of defoliation indicate that your control can be achieved by planting resistant genotypes. In order to guide breeding programs and to predict the stability of resistance is essential to understand the genetic control of resistance in eucalyptus to defoliation. Thus, the objectives of this paper were to map QTLs (Quantitative Trait Loci) associated with resistance to defoliation in a Eucalyptus urophylla x E. camaldulensis (EU11 x EC06) family and validate microsatellite markers linked to QTLs in four unrelated pedigrees involving different Eucalyptus species. Defoliation was evaluated on the branches of the lower third of the plants inoculated under controlled conditions. We identified five QTLS for resistance to defoliation (Rd), three on the map of the parental EU11, Rd-1 and Rd-2 located on linkage group (LG) 1 and Rd-4 located on LG6; and two QTLs located on the map of the parental EC06, present in LG2 (Rd-3) and LG8 (Rd-5). Markers linked to QTLRd-2 were validated in two unrelated families by simple linear regression analysis. This is the first genomic map of QTLS associated with resistance to defoliation caused by C. pteridis in Eucalyptus.

Due to its fast growth rate and little nursery requirements, willow is largely planted as short rotation coppice species for bioenergy resources in temperate regions. Willow coppices can be easily established by vegetative propagation of cuttings and can remain productive for up to 25 years. In China, diploid species S. leucophiaca and S. eiricola L. are two promising willow species that can be used for high biomass plantation. In order to further improve the biomass yield and resistance drought and pests, we tried to create a genetic map to assist willow breeding. S6 F1 individuals from a cross between S. leucophiaca x S. eiricola L. were used to generate a willow genetic map using AFLP and SSR markers. Both Populus and Salix are members of the Salicaceae. They share genomic homologues with high similarity and many common biological traits. As a model species for biological studies in trees, Populus has considerable genetic and genomic resources, which could provide cues for willow study. Five hundred pairs of SSR primers were selected from Populus database for willow analysis; of them successfully generated polymorphic loci between S. leucophiaca x S. eiricola L. In addition, 24 pairs of AFLP primers also succeeded in detecting polymorphic fragments from F1 individuals.
We selected 243 individuals to construct a framework linkage maps of parents using a two-way pseudo-testcross strategy. The linkage map of *S. noeliana* L contains 98 loci, organized in 15 linkage groups with total map distances between 76.7 cM and 209.5 cM. The average map distance between markers is 18.6 cM and the total genetic distance is about 1,810 cM, covering estimated 77.13% of the genome. The linkage map of *S. leucopithecus* contains 60 loci, arranged into 9 groups with map distances between 63.5 cM and 149.1 cM. The average map distance between markers is 19.57 cM, and the total genetic distance is about 1,037 cM, covering estimated 70.3% of the genome.

**BMC Proceedings** 2011, 5(Suppl 7):P30

**Background:** F1 hybrids of *E. grandis* and *E. urophylla* are commonly grown for pulp and paper production in clonal plantations in tropical and subtropical regions. Improving tree growth [1] and wood quality [2] are important objectives in eucalypt breeding programmes. The efficiency of selection for these traits can be enhanced by molecular breeding approaches enabled by high-throughput, genome-wide genotyping technologies and the recent completion of a reference genome sequence for *Eucalyptus* (*E. grandis* V1.0, JGI, http://www.phytozome.net). In this context, interspecific hybrid pedigrees are valuable for quantitative trait locus (QTL) dissection in *Eucalyptus* as there is abundant interspecific variation in such pedigrees. Breeding for wood property traits is mainly focussed on increasing pulp yield per hectare, reducing wood specific consumption (WSC) and increasing the efficiency of downstream processing by the pulp and paper industry. In this study, we are characterizing the genetic architecture of growth and wood quality traits in an interspecific pseudo-backcross mapping population of an F1 hybrid of *E. grandis* and *E. urophylla*.

**Methods:** A pseudo-backcross pedigree was developed by crossing an F1 hybrid (*E. grandis* x *E. urophylla*, GUSAP1, Sappi Forest Research) clone to non-parental individuals of the two parental species. Diameter (cm) at breast height (DBH) and wood basic density were measured at three years in a set of 305 and 319 progeny of the *E. grandis* and *E. urophylla* backcross families, respectively. The backcross progeny were also genotyped with more than 1700 polymorphic Diversity Arrays Technology (DArT) markers. Framework genetic linkage maps were constructed for the *E. grandis*, *E. urophylla* backcross parents using 139 and 127 selected testcross (1:1) DArT markers distributed across the 11 *Eucalyptus* linkage groups spanning 926 cM and 1100 cM, respectively. The framework maps of the F1 hybrid contained 172 and 154 testcross DArT markers spanning 1061 cM and 1036 cM in the *E. grandis* and *E. urophylla* backcross families, respectively. The average map interval of the parental framework maps ranged from 5.6 (F1 hybrid in the *E. grandis* backcross family) to 8.0 (*E. urophylla* backcross parent). DBH of the main stem was measured directly for three-year-old backcross progeny. For the assessment of basic density, a wood disk was taken at a height of 1.5 m. The wood disk from each tree was used to determine basic density by the water displacement method. QTL analysis was conducted using Windows QTL Cartographer using composite interval mapping (CIM) and a genome-wide significance threshold of $\alpha = 0.05$.

**Results and conclusion:** A total of 9 QTLs were identified for DBH and 15 QTLS were identified for basic density (Table 1). These explained 3.1 to 9.6% and 3.6 to 13.1% of the phenotypic variation in the *E. grandis* and *E. urophylla* backcross families, respectively. Higher numbers of QTL were identified in the F1 hybrid parent (15) compared to the backcross parents (9) congruent with the expected interspecific and intraspecific genetic variation segregating in the backcross families. Comparative QTL mapping in the F1 hybrid and backcross parents identified common and unique QTL regions in the parental maps. On LG6 and LG10, QTLs for DBH and basic density were detected in both F1 hybrid maps (*E. grandis* and *E. urophylla* backcross families). On LG4 and LG9, QTLs for density were shared between the *E. urophylla* and F1 hybrid parent, while a QTL for DBH on LG10 was shared between the *E. grandis* and F1 hybrid parents. Overall, six unique genomic regions with QTLs for DBH and eleven QTLs regions for basic density were identified in the two backcross families. The lower number of significant QTLs identified for DBH compared to that for wood basic density (Table 1) is consistent with previous QTL reports and genetic studies showing that wood quality traits have higher heritability than growth traits [2,3]. The genetic maps constructed and QTL regions identified in this study provide a resource for identifying markers for molecular breeding of volume growth and wood density in *E. grandis* x *E. urophylla* hybrids, as well as candidate gene identification based on the recently released *E. grandis* reference genome sequence.

P31 Assessment of SNPs for linkage mapping in Eucalyptus: construction of a consensus SNP/microsatellite map from two unrelated pedigrees

Background: High throughput genotyping of SNP (Single Nucleotide Polymorphisms) based markers has been developed for an increasing number of plant and animal species. In forest trees large scale SNP development has been approached mainly by amplicon resequencing targeting specific genes for association genetics studies. This approach, although successfully employed in conifers aided by the use of haploid tissue, is technically laborious in diploids because of the very high levels of nucleotide and indel diversity in highly heterozygous tree genomes. Direct SNP development from large in silico sequence resources developed by next-generation sequencing is now a very efficient approach for SNP development in forest trees. We have recently developed a first set of 768 SNPs assayed by the Golden Gate Genotyping Technology for the highly heterozygous genome of Eucalyptus from a mixed Sanger/454 database [1]. We saw that a careful sequence quality assessment and the application of stringent constraints on the SNP surrounding sequences has a significant impact on SNP genotyping performance and polymorphism. With the exception of 72 SNPs specifically selected in 20 candidate genes putatively associated with relevant wood phenotypes, all remaining validated SNPs were randomly picked based solely on in silico quality. In this study we wanted to position these SNPs relative to microsatellites and assess their information content for linkage map construction. To enhance our ability of mapping SNPs we employed two eucalyptus full-sib families involving four different Eucalyptus species.

Material and methods: Two inter-specific segregating populations of Eucalyptus, population IP (E. grandis x E. urophylla) and DGUGL (E. dunnii x E. grandis) (E. urophylla x E. globulus) were used for linkage analysis and map construction. DNA was extracted through CTAB and picogreen were quantified. The DNA was used for SNP genotyping on an Illumina BeadStation 500 GX. SNP data were analyzed using GenomeStudio V2009.1 and a GeneTrain score cutoff of 0.25 and call rate ≤0.95 were initially applied to the whole dataset. After that, every single SNP was manually checked for genotyping failures and potential calling errors that would bias the overall analysis and segregation ratios. Linkage analysis, individual and consensus map construction for both segregating populations was performed using Joinmap, v. 3.0 [2].

Results: The proportion of informative segregating SNPs out of the 768 assayed were similar in the two populations: 215 SNPs in DGUGL (28%) and 239 in IP (31%). SNPs were mapped at regular intervals will be necessary for broader applications. For example, to implement Genomic Selection in most Eucalyptus breeding programs some 4,500 to 6,000 informative SNPs will be necessary to provide a marker density of 3 to 5 markers/centiMorgan and reach selection accuracies above 70% [3]. This would require a SNP panel of some 9,000 to 12,000 SNPs. While this goal is fully achievable, per sample genotyping cost issues, however, will have to be considered before larger scale SNP developments are undertaken in Eucalyptus. Benchmarking the Golden Gate or Infinium genotyping technologies against other high throughput systems such as DArT and emerging genotyping-by-sequencing methods will eventually define how SNP variants will be assayed in Eucalyptus and for that matter in several other highly heterozygous forest tree species.

Conclusions: This study shows that large numbers of informative SNPs can be developed directly from in silico sequence databases involving unrelated individuals to the parents of mapping populations. Evidently, by being biallelic, SNPs will be less efficient than multiallelic microsatellites for linkage mapping purposes. This drawback however is clearly compensated by the much higher throughput, automation and lower cost of SNP genotyping. While this is the first reported sizeable scale SNP mapping effort in Eucalyptus, a larger number of informative SNPs mapped at regular intervals will be necessary for broader applications. For example, to implement Genomic Selection in most Eucalyptus breeding programs some 4,500 to 6,000 informative SNPs will be necessary to provide a marker density of 3 to 5 markers/centiMorgan and reach selection accuracies above 70% [3]. This would require a SNP panel of some 9,000 to 12,000 SNPs. While this goal is fully achievable, per sample genotyping cost issues, however, will have to be considered before larger scale SNP developments are undertaken in Eucalyptus. Benchmarking the Golden Gate or Infinium genotyping technologies against other high throughput systems such as DArT and emerging genotyping-by-sequencing methods will eventually define how SNP variants will be assayed in Eucalyptus and for that matter in several other highly heterozygous forest tree species.

P32 Identification of a novel QTl contributing to rust resistance in Eucalyptus

Background: The genus Eucalyptus has many species that are well adapted to a wide range of environmental conditions in Brazil. However, in some areas diseases are a limiting factor, among which the Eucalyptus rust caused by Puccinia psidii Winter stands out as a destructive pathogen of the Myrtaceae. The growth of plants with high levels of infection is severely compromised and these plants end up being dominated by adjacent plants which ultimately leads to their death. The most efficient method to control the disease is through the use of resistant genotypes. A major effect rust resistance QTL has already been identified [1,2], however a residual variance stays unexplained. In this context, our study aimed to identify genomic regions containing quantitative resistance loci to rust based on segregation data of a S1 progeny from an inter-specific (Eucalyptus grandis X E. urophylla) resistant clone.

Material and methods: The progeny used in this study was generated by the breeding program of Fibria and is composed of 90 S1 trees from the self-pollination of an E. grandis X E. urophylla hybrid tree. This hybrid (VCP-R) is heterozygous for a rust resistance locus [3]and highly resistant to rust. The plants were evaluated at two different sites with high incidence of the disease in November 2010. Four disease severity evaluations were made at 90, 120, 150 and 180 days after planting by scoring the levels of disease using a four-score severity scale. Scores were used to calculate the area under the disease progress curve (AUDPC) for each plant and for BLUPs estimation. Genomic DNA was CTAB extracted from healthy young leaves and used in PCR amplifications of 121 microsatellite, 20 TRAP and 38 AFLP markers (totalizing 179 markers).
The Onemap software [4] was used in linkage analysis. The estimated BLUPs were used in QTL mapping [5]. The QTLs were mapped by interval mapping (IM) and composite interval mapping (CIM).

**Results:** Linkage analysis resulted in 11 linkage groups with 160 linked markers. The identity of the groups were as in [6] based on common microsatellite loci as references. The length of the map was 1075 cM with an average distance of 6.7 cM. IM analysis identified one QTL in linkage group 3 (LOD=7.7) with a large phenotypic effect that accounted for 28.5% of the variation (fig. 1). The negative additive effect was significant (p = 0.05), without dominance effects. QTL was located 1.6 cm from SSR EMBRA049 and 5.8 cm from AFLP E08M18_250. The CIM analysis mapped two QTLs, both located in linkage group 3. The peak LOD score (LOD=10.3) of QTL1, which explained 39.5% of the phenotypic variation, mapped in the same interval of the QTL identified in the IM analysis. It was located close to Embr4049 (1.6 cm) and presented significant negative additive effects and no significant dominance effect. The second QTL (QTL2), with LOD=3.4, had a relative lower phenotypic effect (6.9%), mapped 3.1 cm close to the AFLP marker E08M18_300 AFLP. However, differently than QTL1, QTL2 presented both additive and dominance effects.

**Conclusions:** The use of the AUDPC permitted to transform discrete variables (symptoms scores) into a continuous variable, which gives greater power in QTL detection. The effect of the reduced size of the S1 progeny in QTL detection was compensated by the BLUPs analysis, which considers only the genetic variation in QTL localization. QTL mapping was done by two different approaches (IM and CIM) that presented contrasting results. The non detection of QTL2 in the IM analysis was probably due to the limitations of the method (e.g., non-independence in different intervals when there are more than one QTL and low precision of the position by the presence of linked QTLs). Previous studies on the inheritance of resistance to rust in eucalyptus identified a locus with large phenotypic effect, but also pointed to the existence of minor effects [1,2]. Our results confirm the hypothesis of the presence of at least one minor effect locus, by data analysis in quantitative approach and CIM, as never used before in Eucalyptus rust resistance mapping. This work revealed the existence of a second rust resistance locus in addition to one with large effect locus previously mapped in linkage group 3. The identification of markers linked to resistance loci gives perspectives of MAS of resistant genotypes, which is desirable in the case of this disease due to the technical and economical difficulties of selecting resistant genotypes based solely on phenotypes since this biotrophic requires large areas and skilled labor. In addition this study opens possibilities for the positional cloning of the resistance genes together with the availability of the genome sequence of eucalyptus.

E-mail: smarucci@cnia.inta.gov.ar

BMC Proceedings 2011, 5(Suppl 7):P33

Background: The Biotech MERCOSUR project (85% founded by the European Union) launched in January 2009 and finished in December 2010. The general objective was to establish a regional scientific-technological network to develop a genotyping and phenotyping platform useful for the improvement of *Eucalyptus* in the region. Two advanced genetic strategies (genetic and association mapping) were applied to investigate the genetic basis of the industrial wood formation and energy production of *Eucalyptus* plantations. Up to date, no projects were carried out involving the four MERCOSUR countries altogether. The project brought together scientists from 3 MERCOSUR public research institutes and 2 industrial partners from 4 countries.

The project was possible thanks to the availability of five evaluated field trials of *Eucalyptus*, four segregating populations, a high-density Diversity Arrays Technology (DA'T) resource of wide genome coverage and high transferability technology for the genera [1], as well as phenotypic assessment methods of physical and chemical properties of wood using Near Infrared Reflectance (NIR) [2] together with the classical measurements of growth and wood quality tree properties.

The aim of this work is to present the main inputs and results achieved in the previous 7 years. Materials and methods: Plant material: Open pollinated (OP) progeny trial of *Eucalyptus grandis* planted in Argentina: 188 trees from 132 OP families (1 to 3 trees per OP family) from 13 native stand sites in Australia and 3 Argentinean land races. Clonal trial of *E. grandis* planted in Paraguay: 123 clonal trees most of them with unknown provenances.

OP progeny trials of *E. globulus* planted in Uruguay: 169 trees from 132 OP families (1 to 8 trees per OP family) from 8 Australian geographic races and one Chilean land race. OP progeny trial of *E. globulus* planted in Argentina: 134 trees from 129 OP families (1 or 2 trees per OP family) from 8 Australian geographic races and 2 landraces from Chile and Portugal. Full-sib progeny trial of *E. grandis* planted in Argentina: 130 full-sib trees (see García et al. in this journal). *E. grandis* × *E. urophylla*: described in [3].

Genotyping: Over 7,600 clones of DA'T *Eucalyptus* microarray were screened. From 12 to 19 polymorphic simple sequence repeat (SSR) markers [4] were used to estimate diversity parameters as well as inbreeding coefficients for the *E. grandis* and *E. globulus* populations. For map development, more than 300 SSR markers were tested.

Growth, shape and wood quality tree measurements: Standard methods were used to measure diameter at breast height, total height, stem straightness, pilodyn penetration and basic density for all population analyzed. Chemical wood properties for NIR spectroscopy predictions: Lignin contents was measured by Klasson method, extractives by an adjusted laboratory protocol, Syringyl/Guaiacyl ratio by analytical pyrolysis. Pulp yields were calculated based on the oven-dry weight of wood chips charged to the reactor at Kappa number 18. The NIR spectra were obtained by diffuse reflectance on a Bruker model MPA.

Data analysis: Several tools for data analysis were applied according to the objectives of the different approaches (preliminary association mapping, see Cappa et al.; genetic mapping, see García et al., this journal and [3]).

Results: 1. Germplasm characterization with DA'T markers in two *E. grandis* and two *E. globulus* populations: between 2,300 and 2,816 DA'T (call rate higher than 0.80, and polymorphic for more than 95% of individuals) were included in a preliminary association analysis (Cappa et al. in this volume). 2. Linkage Mapping for QTL detection with DA'T (between 1500 and 2000 segregating markers per population), SSR, EST-SSR and candidate genes in *E. grandis* population (García et al., this volume) and in *E. globulus* × *E. urophylla* [3]. 3. NIR-PLSR models were developed to assess extractives (ethanol and water) and lignin content (Klasson and total) as well as lignin composition (S/G ratio) and pulping yield for *Eucalyptus globulus* and *E. grandis*. All models obtained were at least good enough for screening with RPD above 2 [2]. The RPD obtained varied with trait and species (*E. globulus*: extractives-2.3; Klasson lignin-3.9; total lignin-3.8; S/G-3.8; pulping yield (K18)-3.5; *E. grandis*: extractives-5.9; Klasson lignin-6.5; total lignin-3.2; S/G-4.2).

4. Phenotyping analyses: between 2,000 and 16,000 trees were characterized for 2 to 5 traits (diameter at breast height, total height, stem straightness, pilodyn penetration and basic density). This data for all populations is available as a product of the project. The phenotypic distribution of all continuous traits was studied. Then, to deal with environmental variation, the data were analysed using a mixed linear model with separable first-order autoregressive residuals for rows and columns (i.e., with a standard spatial analysis).

5. Generation of clonal populations in Argentina and Uruguay for future association mapping studies: two *E. globulus* and one *E. grandis* (> 200 each) for a more precise and thorough evaluation of phenotypes are being planted.

6. Origin assign for clone trees of unknown provenances. This was possible due to the combination of DA'T markers analysis with population structure approaches. More than 50 clones were assigned to defined clusters.

7. Training of the participants involved: 4 lab training and 2 courses were developed for different participants of the project.

Conclusions: The genotyping and phenotyping platform was successfully established and encourage the collaboration between the participants of the different countries. Likewise different strategies have established the platform for developing new works in the near future using the resources and tools generated in the context of the Biotech MERCOSUR project.

A new set of 182 microsatellites for Eucalyptus: characterization and mapping in a four-species consensus linkage map

P34

Background: Eucalyptus is the most widely planted hardwood crop in the tropical and subtropical world. Plantations of Eucalyptus species supply high-quality wood for industrial applications and are important sources of carbon neutral renewable energy in Brazil. E. grandis and E. urophylla and their hybrids are the most widely planted species in fast growing commercial forests in Brazil. E. globulus is the preferred raw material by the mills generating a pulp that is considered superior by the market. However as a pure species it does not grow adequately in Brazil but performs well in hybrid combinations. Breeding programs have increasingly incorporated E. globulus germplasm in fast moving elite populations. Molecular breeding in such populations will require information on markers, comparative mapping and QTL validation across pedigrees involving these different species. Highly multiallelic and transferable microsatellites not only are excellent tools for individual identification, but also provide robust and efficient framework genetic maps that serve well for mapping thousands of biallelic higher throughput markers such as Single Nucleotide Polymorphisms (SNPs) and Diversity Array Technology (DArT). Furthermore microsatellites provide a powerful way for QTL validation across species. We describe the development and characterization of 182 new microsatellites, most of them derived from ESTs and some from a genomic shotgun library. These markers, together with other previously developed ones were used to build a consensus map involving three different pedigrees derived from intercrossing four species of Eucalyptus.

Methods: The source of ESTs used to mine microsatellites and the methods used to select loci and design primers were described earlier [1,2]. Data from a sample sequencing experiment, carried out back in 2003 using a Sanger sequenced shotgun genomic library, was used for microsatellite discovery (R.T. Lourenço, unpublished). Microsatellite, primer pairs were initially screened for assay success, polymorphism and inter-specific transferability by colorimetric detection on polyacrylamide gels. Selected loci had their forward primer re-synthesized with a fluorescence label and used in downstream genotyping. Loci were characterized using a set of 32 unrelated individuals each of E. grandis and E. globulus. Map construction was carried out for three different pedigrees of Eucalyptus one of them being the pedigree used for a reference map construction [3]. Mapping was conducted using JoinMap 3.0 [4] with a minimum LOD score of 10. and marker order determined with the default mapping module parameters. Parameters of genetic information content (PIC polymorphism information content; PE = probability of paternity exclusion and PI = probability of identity) were estimated for all newly developed microsatellite markers for each species separately.

Results: Data mining of 22,298 unigenes provided 1,261 microsatellite loci. Most of them were (54.71%) trinucleotide repeats. After all screening steps, 494 microsatellites amplified discrete and polymorphic fragments and 210 were selected for fluorescence based genotyping. From the single-pass genomic shotgun library 41 microsatellites were also selected following the same screening steps. Genetic maps were initially built for each pedigree separately. A consensus map was then built by combining separately the homologous linkage groups of the three maps. The total number of microsatellite markers eventually mapped was 448 including the 234 previously mapped [3] and part of those published but not yet mapped earlier [1,2]. The map had an estimated total recombination distance of 1,297 cM and an average distance between adjacent markers of 3.48 cM. The linear order of markers was conserved on most linkage groups across the individual pedigrees and the consensus map with no evidence of rearrangement of chromosomal blocks. For the 182 newly developed microsatellites characterized the allele size range did not vary between E. grandis and E. globulus. Only 15 loci for E. grandis and 17 loci for E. globulus were monomorphic in the set of individuals genotyped. The average number of alleles was very close in the two species, 4.6 for E. grandis and 4.8 for E. globulus. A significant estimate of null allele frequency was found for only seven loci and these coincided for the two species Average PIC, PE and PI for the set of loci were not substantially different between the two species. Furthermore the overall performance of the EST derived and genomic shotgun derived sets of microsatellite did not show any appreciable difference, somehow unexpectedly due to the generally lower polymorphism of genic microsatellites. The ascertainment bias introduced by the much larger set of EST derived microsatellites and rigorous screening applied might have contributed to this.

Conclusion: This work summarizes the development and characterization of a new set of 182 new microsatellites markers and presents a relatively dense microsatellite marker consensus map involving four different species of Eucalyptus. The new 182 microsatellites developed are robust and polymorphic enough to be used for applications in breeding programs that involve individual identification as well as for comparative QTL mapping and marker assisted selection.

Background: Genetic linkage maps have been essential tools to examine the inheritance of qualitative and quantitative traits, to carry out comparative mapping and to provide markers for molecular breeding applications. Linkage maps for species of Eucalyptus have been reported for several pedigrees using different molecular marker technologies [1]. However improved marker density, throughput and transferability across species are necessary to increase resolution of current maps for a variety of genomic applications. We report the development of a high density linkage map for Eucalyptus based on microsatellites and DArT (Diversity Arrays Technology) markers generated by a standardized genotyping microarray [2]. DNA probes that constitute the DArT microarray were sequenced and positioned on the reference Eucalyptus genome to provide information about their sequence content, their distribution relative to annotated genes as well as the relationship between physical and recombination distance in the Eucalyptus genome.

Methods: Map construction was carried out using an F1 progeny of 177 individuals derived from a cross between E. grandis and E. urophylla. Genomic representations of both parents and their F1 offspring were produced with the same complexity reduction method used to prepare the library (PstI/TaqI) generating the ‘targets’ for hybridizing to the arrays. Microarray imaging, data extraction polymorphism detection and marker scoring were carried out using DArTSoft v7.44 (http://www.diversityarrays.com/). Polymorphic markers were filtered according to reproducibility, quality parameter (Q) and marker call rate as described earlier [2]. An integrated linkage map was constructed with JoinMap v3.0 [3] using a framework map of previously mapped fully informative anchor microsatellites. All 7,680 DNA probes that constitute the current DArT genotyping microarray were Sanger sequenced. Redundancy analysis was carried out at the sequence level using a 50bp minimum overlap, 99% identity, and allowing for 10% mismatch and a gap size of 20bp. DArT probes that matched more than 100bp to the annotated Eucalyptus reference genome as available in Phytozone. Distribution of DArT probes and mapped DArT markers relative to the predicted gene models was carried out by dividing the genome in 500 kbp bins corresponding approximately to a 1 cM recombination fraction.

Results: A segregation ratio filtering (both for 1:1 and 3:1 markers) together with a relaxed call rate threshold > 50% were initially applied to include the largest number of potentially mappable markers. A total of 4,271 DArT markers segregated 1:1 and 1,572 segregated 3:1. The complete dataset with 6,065 markers (5,843 DArT and 222 microsatellites) was submitted to a linkage analysis resulting in eleven groups at LOD ≥ 15 with a total of 2,484 markers. A subset of 1,032 markers positioned at high likelihood for ordering (864 DArTs and 168 microsatellites) provided a framework map with 1,176 cM and an average recombination distance between consecutive markers of 1.15 cM. When all the 2,484 mapped markers were fitted, the total recombining genome length increased to 1,303 cM with a resolution of 0.6 cM. A redundancy analysis of the 6,918 DArT probes for which sequences could be obtained resulted in 4,583 unique sequences (66%). The establishment of 34% representative of the random DArT probes found alternative probes for detecting polymorphism in the same genomic region in different individuals. A total of 6,480 probes (93.7%) were confidently mapped onto the reference genome; 4,189 of them (65%) mapped to single positions while the remaining 2,291 probes mapped to a second position with a relatively high suboptimal alignment score and were therefore considered mapped at lower confidence. About 50% of these low confidence mapping (1,026) actually mapped to a sequence position containing a repeat element which might explain the mapping result. A total of 438 DArT probes could not be mapped to the current assembly. These DArT probes might further improve the current genome version by including some yet unassembled genome contigs. A total of 1,987 linkage mapped DArT markers for which sequence was available were positioned relative to the 41,208 gene models in the current genome, distributed in 500 kbp bins providing an average of 1.6 ± 2.4 DArT markers for the 34 ± 15 gene models present in each genome bin. Interestingly a total of 4,663 DArT probes (67%) mapped at less than ten basepairs from the nearest gene model and only 76 probes mapped at more than 10kbp. The largest distance of a probe to the nearest gene model was only 156 kbp and a modest although highly significant coincidence across the whole genome was seen between the number of DArT markers and the number of gene models (Spearman rank correlation R = 0.33 p<0.0001).

Conclusions: The linkage map presented in this work was used to aid the ordering of contigs during the assembly of the Eucalyptus grandis genome currently available through the JGI Phytozone website. This map, together with other parallel mapping efforts that used this same genotyping platform have provided between 2,000 and 3,000 segregating markers irrespective of species of Eucalyptus. The mapping density achieved with the Eucalyptus DArT microarray provides unprecedented opportunities for comparative mapping across pedigrees, high resolution QTL analysis and molecular breeding applications across species of the genus. We have shown that not only the DArT marker sequences are highly enriched for genes, but that their distribution relative to the predicted gene models provides an extremely efficient tool to specifically tag genes at distances within the extent of LD in typical breeding populations. The use of this standardized high-throughput genotyping platform will therefore be instrumental to implement genome-wide selection strategies and positional cloning efforts in multiple Eucalyptus species.

Development of highly-multiplexed SNP arrays in maritime pine for multi-objective genetic applications
C Plomion1, E Chancerel1, C Lepoittevin1, I Lesur1, SG Gonzalez-Martinez1, GG Vendramin1, MT Cervera2
1INRA, UMR1202 BIOGECO, France; 2INRA, Center of Forest Research (CIFOR), Indonesia.

Single Nucleotide Polymorphisms (SNPs) are the most abundant form of genetic variation in the genome. In this poster, we reviewed what has been achieved in terms of highly-multiplexed SNP genotyping assay construction in maritime pine (Pinus pinaster Ait.), the main conifer used for commercial plantation in southwestern Europe. Seven custom SNP-assays (384 and 1536-plex), oriented towards broad applications, have been designed. We illustrated here the usefulness of this genotyping technology to address specific questions related to i/ genetic diversity and population structure analysis, ii/ linkage and QTL mapping and iii/ association mapping. With respect to genetic diversity and differentiation, a custom VeraCode assay for 384 SNPs mostly based on a larger array designed for linkage mapping (see below) allowed to obtain less blurred, albeit similar, breeding zone boundaries than a set of 12 nSSRs screened on the same individuals. Levels of diversity were also more accurately estimated, showing clear differences among gene pools. Interestingly, a relatively small subset of SNPs would be enough to develop an application tool for origin certification, which could have a notable impact on current operational practices. In terms of linkage mapping, a custom GoldenGate assay for 1,536 SNPs detected through the resequencing of 500k SNPs (in vitro SNPs) and from Sanger-derived Expressed Sequenced Tags (in silico SNPs) was established. Offspring from two mapping pedigrees were genotyped. A consensus map comprising 357 SNPs from 292 different loci was constructed and the analysis of sequence homology between mapped markers and their orthologs in a Pinus taeda linkage map, made it possible to align the 156 linkage groups of both species. Moreover, QTL detection for different traits is underway. In terms of association mapping, a custom GoldenGate assay with 384 SNPs was built and used to genotype 160 unrelated plus-trees from a half-sib experimental design for which breeding values (for height growth, circumference, stem straightness at 8 years, lignin content and extractives at 31 years) were available. Taking into account multiple...
testing, one single SNP in a gene encoding a putative fasciclin-like arabinogalactan protein was found to be associated with growth traits. We conclude that the VeraCode/GoldenGate assays can be used successfully for high-throughput SNP genotyping in maritime pine, a conifer species that has a genome seven times the size of the human genome. This first generation of SNP-arrays has been recently upgraded to an Infinium-array (containing 10.5k SNPs) thanks to deep sequencing based on new generation sequencing technologies. The Infinium-array also includes SNPs from comparative orthologous sequences with other major conifer species, providing a wider collection of anchor points for comparative genomics among these major groups of forest trees.

E-mail: carols@cenargen.embrapa.br

**Background:** QTL mapping is an unbiased approach where the phenotype reveals the location of regulatory genes or genomic regions affecting the trait of interest. The development of transferable molecular markers and the increased use of multiple pedigrees for QTL mapping have allowed comparative analysis of QTLS across independent studies thus providing validation data. Such QTL positional information, together with the availability of annotated genome sequences, now promises to identify strong candidate genes for a number of traits [1]. As large pedigrees become available and higher resolution mapping with SNPs, DArT and genotype-by-sequencing technologies becomes routine in forest trees, QTL positional information could be an alternative to the current approaches that rely on tentative candidate genes for association genetics studies. Among the several traits for which QTLS have been mapped in forest trees those that display higher heritability, such as wood chemical composition, are more likely to involve candidate genes of stronger effect although recent association studies show that even such genes explain very small proportion of the variation [2]. In this study we used a high-resolution map with over 2,000 Diversity Arrays Technology (DArT) markers to carry out an initial assessment of the number of annotated gene models in the reference genome sequence of Eucalyptus that putatively co-locate to carry out an initial assessment of the number of annotated gene models in the reference genome sequence of Eucalyptus that putatively co-locate to QTLs for growth and wood quality traits.

**Methods:** A QTL mapping study was carried out with a clonally replicated segregating population of 171 F1 individuals derived from an E. grandis x E. urophylla cross. Individuals were genotyped with the Eucalyptus DArT microarray described earlier [3]. The DArT marker data were combined with 222 microsatellites and a linkage map for each parent was constructed using JoinMap 3.0 [4]. Six traits were measured: height growth (HG), circumference at breast height (CBH); wood specific gravity (WSG); cellulose pulp yield (%PULP); Total Lignin (TL); syringyl/guaiacyl ratio (S/G). QTL mapping was carried out using QTL Cartographer [5] on the two parental maps separately at 1 CM intervals. Empirical threshold significance levels for QTL detection were determined by 1,000 permutations considering a significance level of 5%. All the segregating DArT and microsatellite markers were mapped onto the 11 pseudo-molecules of the Eucalyptus grandis draft genome sequence covering 609 Mbp.

**Results:** QTL analyses were carried out using framework genetic linkage maps with high likelihood support for order. The maternal map had 825 markers (684 DArTs + 141 SSR) and the paternal map 511 markers (410 DArTs + 101 SSR). In total 16 QTLS for E. grandis and 14 in E. urophylla were detected influencing growth and wood quality traits. High and significant positive phenotypic correlations were found between CBH and HG, TL and S/G, and S/G and %PULP. In the maternal E. grandis map, five QTLS were identified for TL (Linkage groups (LG) 1, 3, 4, 5 and 8), two QTLS for %PULP (LG 4 and 5), three for S/G (LG 5, 8 and 10), WSG (LG 6, 8 and 10) and HG (LG 1, 2 and 6). In the E. urophylla paternal map we detected three QTLS for %PULP (LG 1, 4 and 9), three for HG (LG 7, 8 and 10), two for CBH (LG 7 and 10), two for S/G (LG 8 and 9), and one for WSG (LG 8). More than two QTLS were clustered on LG 4, 5 and 8 in E. grandis and on LG 4, 8 and 9 in E. urophylla suggesting interesting genomic regions to look for candidate genes to be tested in association mapping. Several of these QTLS were syntenic to QTLS found in other studies [6,7] providing some indirect support for their validity. The sequences of DArT and microsatellite markers bracketing QTLS were used to extract the gene models from the Eucalyptus reference genome. A total of 7,125 predicted gene models are found across all maternal QTLS, with an average of 445 genes per QTL. For the paternal QTLS 5,076 gene models exist, with an average of 362 genes per QTL.

**Conclusions:** As in many other QTL mapping studies in Eucalyptus (6-8) we have identified several QTLS that control a modest proportion of the phenotypic variation for a number of economically important traits. In this first assessment of putative candidate genes co-locating with these QTLS we found thousands of annotated gene models, hundreds of which could be tentatively suggested as being involved in trait variation. Notwithstanding the low mapping resolution provided by the small progeny, this preliminary study shows that tens or hundreds of genes will likely be always found underlying QTLS for such complex traits. Testing and validation of such large numbers of genes will require a gigantic effort. Furthermore a large proportion of the phenotypic variation remains unexplained by the few QTLS mapped. It is therefore questionable from the applied stand point how much useful information this approach will effectively provide for the advancement of association genetics and, for that matter, of breeding practice.

**BMC Proceedings 2011, 5(Suppl 7):P38**

Traits related to local adaptation by definition show high phenotypic differentiation. The underlying genetic patterns could be clines at individual loci or small effects and extensive linkage disequilibrium at the underlying loci. In any case, including many populations in an analysis provides more information, but may simultaneously induce problems due to genetic structure. Even if neutral loci have little genetic structure, loci related to other clinically selected traits could show more structure.
Here we have developed an approach to efficiently use the information along a latitudinal environmental gradient. Scots pine populations from central Europe to the species’ northern range were sampled and patterns of phenotypic variation of both timing of budset and frost tolerance were measured in common garden experiments, (10 populations, a total of 270 half-sib families, 25 trees per family). By hierarchical modelling of the phenotype’s clinal variation and accounting for varying allele frequencies across the 10 populations, the statistical approach simultaneously exploits the genetic variation between and within populations to detect association signals. We apply shrinkage-based Bayesian variable selection to detect genetic associations among timing of bud set and ~450 SNPs in Scots pine.

P39 Development of a genetic linkage map of rubber tree (Hevea brasiliensis) based on microsatellite markers
Lívia Moura Souza1, Camila Campos Mantello1, Fernando Suzuki1, Rodrigo Gazaffi2, Dominique Garcia3, Vincent Le Guen4, Antonio Augusto Franco Garcia5, Ane Cézar Pereira Souza1
1Molecular Biology Center and Genetic Engineering, UNICAMP, Campinas, SP, 13083-875, Brazil; 2Department of Genetics “Luiz de Queiroz” College of Agriculture University of São Paulo, Piracicaba, SP 13400-000, Brazil; 3UMR ARGP, Montpellier, Cedex 5, France; 4Department of Plant Biology – Biology Institute and Molecular Biology Center and Genetic Engineering, UNICAMP, Campinas, SP, 13083-875, Brazil; 5E-mail: liviamoura31@gmail.com

Background: Rubber tree (Hevea spp.) is the main natural rubber producing crop, and it is cultivated in numerous equatorial, tropical and subtropical areas. Hevea spp. is an outcrossing perennial species and belongs to the botanical family Euphorbiaceae. Breeding of rubber tree, like for many other tree crops, is a long term process. Large scale cultivation of a new cultivar can only be reached after 20–25 years of field experiments on large areas. Breeders are thus interested in developing alternative strategies to improve and speed up the breeding scheme, using genetic markers. Molecular markers are being used for more than 15 years in Hevea breeding, mostly for diversity studies, assessment of genetic distance among cultivars, genetic mapping and identification of genetic loci implied in the expression of agronomical traits.

Material and methods: The mapping population was a full-sib progeny (F1 progeny) derived from a controlled cross between the cultivars PB217 and PR255. The PB217 has a high yield potential, which is expressed throughout the lifetime of its rubber production, low metabolic activity and a high level of sucrose in the latex vessels. Genetic population PR255 showed tolerance to injury and cold. A set of 603 microsatellite primer pairs was tested for polymorphism in the two parents and six F1 progenies genotypes. Among these, 200 genomic microsatellites have been developed by our laboratory (part published in [7]). 178 EST-SSRs were obtained from a published work [1]. The polymorphic microsatellites between the parents were selected for mapping in a F1 population. The PCR conditions were detailed by [7]. PCR products were separated using a DNA analyzer 4300 (LI-COR) through 6.5% polyacrylamide gels. Linkage map was obtained using OneMap [5]. This software generates integrated genetic maps from molecular markers with different segregation patterns; it considers multipoint technology based on Hidden Markov Models, as presented by [8]. LOD Score 4.5 and recombination fraction of 0.40 was considered to determine linkage between markers. The algorithms “compare” (until six markers) and “order” (more than six) were applied to obtain best order for each linkage groups, as presented in mapmaker/EXP [6].

Results and discussion: Out of 603 microsatellites markers evaluated, 309 (51%) showed polymorphism between the parents of the mapping population. Until now, 225 marks were genotyped (59 SSR genomic loci and 166 EST-SSRs). Chi-square test was carried out on the constructed genetic polymorphic loci showed that 110 loci followed a segregation ratio of 1:1, 28 followed a ratio of 1:2:1 and 87 (38.7%) followed a ratio of 1:1:1. The map consists of 225 markers, distributed in 23 linkage groups (LG) and 2,471.2 cM in length with an average genetic distance of 11 cM between adjacent markers. The largest group has 215.9 cM (18 markers) and the smallest has 10.27 cM (2 markers). This reflects in a more realistic way the polymorphism of the full-sib cross.

In a previous work [4] a linkage map was constructed from a double pseudo testcross, and two maps were constructed separately for each parent. In the present work, instead of using only single dose markers (1:1) like [4], markers that segregate in both parents in the ratio 1:2:1 and 1:1:1 were also used enabling the construction of an integrated genetic map and facilitating the location of quantitative trait loci (QTL) [2]. Seven linkage groups are small, composed of two or three markers and covering a few cM. These small linkage groups probably occur because the map is not saturated enough and some chromosomes regions could not be linked. The chromosome number accepted today, for most Hevea species, is 18 ([24], [36], as observed by [4]).

Conclusions: This map is still under development and we expect to achieve a saturated map consisting of 18 linkage groups. The present map will be used for yield rubber QTL mapping and other important economical characteristics.

E-mail: amissiaggia@fibria.com.br
BMC Proceedings 2011, 5(Suppl 7):P40

Background: Drought stress is one of the most important abiotic factors in Eucalyptus sp. plantations which influences the growth and limits productivity in cultivated areas, mainly in central, northern and northeastern areas in Brazil, where large parts of these areas have limitations on water supply. The breeders are now looking for tolerant genotypes to overcome this challenge and the QTL mapping approach will help to understand the genetic control of drought tolerance. The objective of this study was to identify genetic loci controlling the phenotypic variation in drought tolerance in a Eucalyptus segregant progeny grown under drought and irrigation conditions.

Material and methods: The progeny used in this study was generated by the breeding program of Fibria Celulose and is composed of 184 F1 genotypes from a cross between a tolerant and a susceptible clone to water stress, both E. grandis x E. urophylla hybrid tree. In a greenhouse condition, the progeny (seedlings with 70 days) was evaluated under two irrigation conditions (1 - control: assigned to a well-watered regime with watering equal to transpiration loss and 2: submitted to water deficit until the onset of initial drought symptoms) in 4 different experiments. Growth (the relative increase in height and stem diameter; leaf number;
Results and discussion: Linkage analysis resulted in 11 linkage groups with 101 markers. The groups were identified using a reference eucalyptus genetic map [3], through common microsatellite loci. The length of the map was 770 cM with an average distance of 7.2 cM between markers. The experimental design allowed analysis of genotype by drought tolerance interaction for the first time in a eucalyptus QTL mapping population, resulting in the identification of 66 loci that control traits under water restriction and 70 loci under irrigation condition, for all of 16 traits evaluated (considering LOD>3.0). Both additive and dominance effects were detected. Around 4 – 7 QTLs were identified for each trait and, in general, the QTLs identified explained from 11% to 30% of phenotypic variation, except by photochemical efficiency, where 59% of phenotypic variation was explained, mainly by 2 QTLs (25.16% and 25.17% and peak LOD score 3.46 and 18.73) mapped in linkage group 6. Most of QTLs identified were specific for each treatment and for just two traits (root and leaf dry weight) QTLs were co-localized for both irrigation conditions and they were mapped in linkage groups 2, 8, 10 and 11. Clusters of QTL for different traits were mapped close to each other at several linkage groups, indicating either a common genetic base or tightly linked QTL. The results are consistent with Ronnberg’s and Yue’s results [4,5], where many QTLs with minor effects are controlling drought tolerance.

Conclusions: This work revealed the existence of several QTLs that control drought tolerance in Eucalyptus and these QTLs identified may be involved in many tolerance mechanisms that plants can use to avoid this stress. Since clusters of QTL for different traits were identified, potential pleiotropic regulators could be coordinating these traits and these genomic regions can be used to identify key genes for these traits.

BMC Proceedings 2011, 5(Suppl 7):P41

Background: Brazil stands on the international scenario by having one of the largest natural forest heritage and extensive sustainable planted forests. Brazilian planted forestry is based mainly on fast growing eucalyptus and pines, with the pulp, paper and steel industries as the major consumers. Introduced commercially in Brazil in the early twentieth century, the eucalyptus have experienced increasing levels of genetic improvement over the years. Along with the classical breeding, the use of genetic markers has positively influenced breeding programs, contributing to quality control processes of clonal forestry and advanced breeding. Microsatellite markers have been the main tool used to date. They are multiallelic, highly polymorphic and thus very efficient for several applications that require identification and discrimination of elite clones and determination of parentage. While di and tri-nucleotide repeat microsatellites tend to be more polymorphic, tetra and higher order repeats allow a more robust allele calling [1]. SNP markers generated by a high-throughput system have been recently developed for Eucalyptus but not yet routinely incorporated in Eucalyptus breeding programs. In spite of their lower genetic information content, many more SNPs can be simultaneously typed using automated systems, an appealing feature to operational breeding programs. The aim of this study was to comparatively evaluate the resolving power and precision of different sets of molecular markers (microsatellites and SNPs) assayed by the Golden Gate technology for the most common operational applications in Eucalyptus breeding programs.

Methods: Samples belonging to six species of Eucalyptus (E. grandis, E. nitens, E. camaldulensis, E. globulus, E. delegatensis and 25 spontaneous Eucalyptus hybrids) were genotyped with three different sets of markers: (1) 24 di- and trinucleotide microsatellites (2) 17 tetra-, penta- and hexanucleotides microsatellites and (3) selected subsets of SNPs from the 768 developed earlier [2]. Microsatellites were genotyped by capillary electrophoresis in an ABI3100 genetic analyser and data collected under dye set D using Genescan/Genotyper.SNP genotyping was performed using an Illumina BeadStation 500 GX at the Genome of the University of Florida and the data analyzed using the software GenomeStudio. Multilocus genotypes were obtained with the two microsatellite panels and a set of the 96 most informative SNPs for individual identification based on an algorithm that takes into account minimum allele frequency and observed heterozygosity within and across species. The genotype data were used to estimate the combined probability of paternity exclusion (PE) and probability of identity (PI) for the marker panels. Additionally, markers were assessed for their ability to estimate genomic ancestry of individuals, a particularly useful application for determining the origin of spontaneous Eucalyptus hybrids. All typed individuals were assigned probabilistically to a given number of populations inferred with a Bayesian approach without any prior population information using the STRUCTURE package [3]. The analyses were performed with each set of microsatellites and with a specific subset of 96 ancestry informative SNPs, selected with an algorithm that focused on SNPs that display contrasting allele frequencies among species.

Results: The panel of di- and trinucleotide microsatellites showed the fastest increase in the combined paternity exclusion with the addition of new markers. For example, a PE > 99% was achieved with only five markers in E. grandis. The panel of tetra-, penta- and hexanucleotide microsatellite was unable to reach a PE of 99% even with all 17 markers were used. The panel of 96 SNPs showed a slower increase in the combined paternity exclusion with the addition of new markers, but needed only 35 markers to reach a PE > 99%. The markers for this was observed with the estimate of probability of identity. In the analysis of genetic structure, all three sets of markers correctly inferred the six genetically distinct populations, corresponding to the six species studied. Furthermore, both panels assigned correctly all individuals to their respective species. The SNP panel showed the highest average proportion of correct assignment for all six species, followed by the di- and trinucleotides and at last the tetra-, penta- and hexanucleotide panel, although these estimates were not statistically different between the three marker panels tested, (p = 0.327).

Conclusions: Results show that di- and trinucleotide microsatellites tested are around three times more informative than the tetra-, penta- and hexanucleotide microsatellites used and about seven times more informative than the specific SNPs employed for assessment of parentage and individual identification. Although more informative, the di- and trinucleotide microsatellites are subject to a higher inaccuracy in allele calling, which can result in inconsistencies across analyses carried out in different labs. All three marker panels showed high resolution power to detect genetic structure and carry out assignment tests in species of...
Eucalyptus. We are now extending this analysis to controlled and spontaneous hybrids to compare the estimates of genomic ancestry provided by the three marker panels. Additionally we are developing much larger sets of SNPs by re-sequencing reduced genomic representations of pooled individuals from all six species. This should allow a targeted sequencing of more ancestral SNPs that are homogeneously polymorphic across species to be used for fingerprinting and parentage or historically more recent SNPs that display contrasting allele frequencies among species and thus be more useful for genomic ancestry determination. We anticipate that despite the lower individual genetic information content, careful selection of SNPs panels for targeted applications coupled to their accurate genotype calling and fast throughput will become an increasingly attractive alternative for operational application in breeding programs.

Background: Knowledge about single nucleotide polymorphism (SNP) markers is extremely important in the development of genotyping assays, allowing improvements in plant breeding through marker-assisted selection. With the emergence of next generation sequencing platforms, high-density SNP discovery in the genome of plant crops becomes more achievable. In this project, we carried out whole genome resequencing of two apple cultivars (M13/91 and Fred Hough, developed by Epagri [1,2]) achieving. In this project, we carried out whole genome resequencing of two apple cultivars (M13/91 and Fred Hough, developed by Epagri [1,2]) using the recently released draft genome sequence of the domesticated apple (Malus x domestica Borkh.) [3] as a reference for SNP discovery.

Materials and methods: We sequenced four DNA samples (two from M13/91 and two from FH cultivars) on four lanes of the Illumina GA II platform (single-end sequencing), with the Illumina PhiX sample used as a control. Image analysis and base calling were performed using on-instrument real time analysis, after which the Off-Line Basecaller was used to convert per-cycle base call files (.bcl) into per read base call files (.qseq). The resulting short reads were aligned to the reference genome with the BWA software [4], with the maximum edit distance set to 3, quality threshold for read trimming set to 15, and no gap opens allowed. Next, SAMtools [5] utilities were used to convert SAM into BAM format, to remove read duplicates and indels, and also to sort reads by coordinates. SNP discovery was then carried out using the GATK Unified Genotyper SNP caller [6].

Results: Alignment of the M13/91 and FH reads to the reference genome resulted in a total of 37,757,897 and 60,400,252 reads mapped, respectively. Considering only reads with root-mean-square mapping quality greater than 20, and occurring at raw read depths (DP) greater than 6 and lower than 20, a total of 143,468 and 474,483 heterozygous putative SNPs were identified when comparing the reference genome with the M13/91 and FH cultivars, respectively. A total of 80,554 heterozygous putative SNPs are shared by both M13/91 and FH cultivars. When considering only homozygous putative SNPs, a total of 20,296 (M13/91) and 70,659 (FH) SNPs were identified. A search was also made between the M13/91 and FH cultivar genomes, resulting in a total of 2,631 SNPs which are homozygous in FH and heterozygous in M13/91, and 4,768 SNPs which are homozygous in M13/91 and heterozygous in FH. In order to determine whether the differences in SNP frequencies between these cultivars are due to differences in read coverage obtained from sequencing, we set up a cut-off value above which all SNP calls in both cultivars had the same coverage, and it showed that their SNP frequency is similar.

Conclusions: We have used next generation sequencing data combined with high-density SNP detection methods to discover large numbers of putative SNPs in apple cultivars, which can be used in the development of genotyping assays.

Eucalyptus globulus Labill. has been used in Spain for decades as a cellulose source for the paper and textile industry. Since 1997, Snacie group has tested new provenances and families from 29 different Eucalyptus species to explore their capacity for biomass and bioenergy production. Plus trees for growth, wood quality, rooting capacity and tolerance to Mycosphaerella sp have been identified by mass selection, and more than 300 controlled crosses among those trees have been carried out. However, the restrictions caused by the high susceptibility to Mycosphaerella leaf
disease and the low rooting capacity of the species *Eucalyptus globulus* Labill. delay the application of the gains to a commercial scale. The objective of this project is to improve the production of *Eucalyptus* in the North of Spain focused on the improvement of two traits of economic importance: clonal/rooting capacity and tolerance to *Mycosphaerella* sp. To achieve this goal three partial objectives have been approached:

**Mass propagation of selected adult clones and rooting improvement by in vitro tissue culture:** Clonal propagation by sequential subcultures of axillary buds in proliferation and elongation media and further rooting of elongated shoots will be developed. This will further optimize a simple in vitro protocol for the micropropagation of identified elite mature trees for raising plantations. Micropropagation will maintain selection gains, developed in improvement programmes, to be transmitted directly to plantations or to seed orchards, adding value to the subsequent products and reducing production costs in the long term. For this purpose, it is required to test differences between in vitro produced trees and seed-derived trees, regarding some important traits such as juvenility, growth, productivity, uniformity and morphological traits.

**Certification of clones and varieties by the use of specific molecular markers:** A collection of 97 elite clones have been genotyped using 22 SSRs [1,2], and four multiplex PCR reactions. This analysis has allowed the genetic characterization of each individual clone, the analysis of genetic similarity among them, and inferring tentative relatedness among clones. This information will be used to improve crossing designs as well as to certify clonal material.

**Genetic dissection of rooting capacity and tolerance to *Mycosphaerella* sp:** A strategy combining transcriptomics, genetic mapping, phenotypic characterization of the targeted traits and QTL analysis has been established. For this purpose a mapping progeny was obtained using two contrasting progenitors: A tree with high rooting capacity, tolerant to *Mycosphaerella* sp, and a tree with low rooting capacity, susceptible to *Mycosphaerella* sp. The steps to reach this goal include: 1) Construction of a cDNA library made of pooled RNAs, from different tissues collected from the progeny plants grown under different conditions. This cDNA library is used as template for Roche GS-FLX Titanium high throughput sequencing. Once the unigene is identified, SNPs from selected genes are chosen to design a 1536 Golden Gate array which is used to genotype both progeny individuals and progenitors. Segregating SNPs are used to construct genetic maps. 2) Evaluation of rooting capacity and response to infection during two consecutive years. 3) Identification of association between SNPs and trait parameters using QTL analysis followed by identification of favourable alleles (SNP variant).

**Acknowledgements:** Financional support for this investigation has been provided by the Ministry of Science and Innovation “Investment fund for employment. Government of Spain” by the CDTI in the project BioSos-CEN-2009-1040 and by the project Eucafuel.

BMC Proceedings 2011, 5(Suppl 7):P44

**Background:** The efficiency of plant breeding depends mainly on two actions of the breeder: creation and subsequent identification of superior genotypes. In both actions, selection plays a fundamental role in the definition of crosses to be performed, with interest in creating new genotypes and identifying superior trees to be used commercially. The great attraction of molecular tools for plant breeding is the direct use of DNA informing in selection, allowing higher efficiency, quickness in obtaining genetic gains with relatively low costs, when compared to the traditional selection based on phenotypic data. All these objectives can be reached through a new approach: genome-wide selection (GWS) or just genomic selection (GS). Genomic selection can be applied in breeding programs of any species. Results obtained in simulated data indicated that GWS can be very profitable in eucalyptus breeding [1]. GWS is based on selection exclusively by molecular markers, after having their genetic effects estimated based on phenotypic data, in a breeding population sample [2]. The present work aims to characterize and estimate genetic parameters of a hybrid progeny test, the population that will compose the genome-wide selection study at International Paper in Brazil.

**Material and methods:** The International Paper Brazil population chosen for genome-wide selection purposes is installed in a Hybrid Progeny Test, comprising 58 crosses from controlled pollination of *Eucalyptus grandis* and *Eucalyptus urophylla* and five common checks (commercial clones of the company), totaling 63 treatments. These 58 families are derived from 56 different parent crosses. The test was installed in July 2006 in Brotas (São Paulo State, Brazil) in randomized complete block design, with six plants per plot and eight blocks, corresponding to a total of 3,024 plants. In 2011 the test was evaluated, performing the measurement of diameter at breast high (DBH) and plant height of the progenies. The obtained data were analyzed in Selegen-REML/BLUP software for the estimation of genetic parameters. The analysis, will allow the identification of the elite individual trees, which comprised the GWS population, ranking the best living trees of the test by estimating the annual average increment and morphological aspects (removing dead, forked and broken trees). Following the selection of the GWS 1,000 trees population, xylem samples were collected and sent for DNA extraction and genotyping with DArT and SNP markers.

**Results:** Three variables were analyzed to characterize the test population: DBH, plant height and wood volume (calculated as function of plant diameter and height). DBH had general mean of 13.8 cm and genotypic variance between progenies of 1.61 cm². The individual narrow-sense heritability of the character was 0.255 ± 0.039, very similar to the plant height heritability of 0.236 ± 0.037. Plant height presented general mean of 21.3 meters and genotypic variance of 2.17 m². The estimated wood volume had general mean of 0.168 m³ per plant and genotypic variance of 0.0012 (m³)². The individual narrow-sense heritability was slightly higher than for DBH and plant height, namely 0.297 ± 0.042. All estimates were typical of quantitative traits controlled by many loci of small effects. Based on the analysis of the experiment, the best trees were selected, as parented clones and parent for crossing. This analysis revealed 44 clones with elite clones, to be used as training/discovery population for GWS purposes. The superior individuals of these crosses were selected to complete 1,000 trees, dispersed through the entire test. The number of crosses (44) selected and the different parents identified (45) are important informations for estimating easily the effective population size (Ne), an important factor in GWS [1].

**Conclusions:** The information and data generated will lead the studies of the next steps into GWS approach. With the deep understanding of the training population that we have, the genomic breeding values (GBV) can be estimated and the GWS applied using phenotypic and marker data simultaneously. A correct choice of a breeding population is essential for traditional plant breeding and is not different in integrated molecular approaches. Subsequently, the wood phenotyping will be performed and the GBV also estimated for wood quality traits. These data will start up the implementation of GWS in International Paper breeding program in Brazil, as operational procedure, looking at quick selection and, consequently, cost decreases.

Background: The availability of next generation sequencing (NGS) technologies has opened the door to new strategies of SNP discovery and genotyping. Rapid genome-wide SNP detection via deep resequencing of reduced representation libraries of restriction digested pools of genomic DNA combined with a reference genome has been successfully used for SNP discovery in microorganisms [1], plants [2] and domestic animals [3]. Taking a step further from using NGS for SNP discovery, Baird et al [1] showed that NGS of short tags derived from barcoded multiplexed genomic representations generated with restriction enzymes could be used for direct genotyping of individuals, calling this method RAD (Restriction-site associated DNA) sequencing. RAD sequencing involves cutting a genome with at least one restriction enzyme and NGS the ends of the resulting fragments. We have recently developed a first set of SNPs for high-throughput genotyping of species of Eucalyptus. Although SNP assay success was high, the proportion of polymorphic SNPs declined as phylogenetic distance between species increased, down to <20% when contrasting E. grandis and E. globulus, the two main worldwide commercially planted species were considered [4]. In this work we used RAD sequencing to discover polymorphic SNPs across these two species. Additionally we were interested in assessing the potential of RAD for direct genotyping-by-sequencing in Eucalyptus. Methods: DNA was extracted separately from 18 unrelated individual trees of E. grandis and 18 of E. globulus. For each species three bulks of six individuals were prepared with equimolar amounts of picogreen quantified DNA. DNA samples were delivered to Floragenex who carried out the RAD reduced representation library preparation using PstI enzyme and NGS the ends of the resulting fragments. We have recently developed a first set of SNPs for high-throughput genotyping of species of Eucalyptus. Although SNP assay success was high, the proportion of polymorphic SNPs declined as phylogenetic distance between species increased, down to <20% when contrasting E. grandis and E. globulus, the two main worldwide commercially planted species were considered [4]. In this work we used RAD sequencing to discover polymorphic SNPs across these two species. Additionally we were interested in assessing the potential of RAD for direct genotyping-by-sequencing in Eucalyptus. Methods: DNA was extracted separately from 18 unrelated individual trees of E. grandis and 18 of E. globulus. For each species three bulks of six individuals were prepared with equimolar amounts of picogreen quantified DNA. DNA samples were delivered to Floragenex who carried out the RAD reduced representation library preparation using PstI and Illumina 75 bp single-end sequencing on a GAIIx. Raw sequence data was filtered for quality and mapped onto the 11 chromosomes of the E. grandis reference genome available in Phytozone. SNPs in the short sequence tags were called for nucleotides with quality Q > 30 at the position and a minimum of 6X coverage.

Results and conclusions: The average sequencing depth exceeded 28X for all bulked samples, providing a minimum estimated ~5X coverage for each individual present in each bulk providing a 93.75% probability of detecting a heterozygous SNP position. With 18 individuals per species (36 chromosomes), the probability of detecting a SNP allele with a Minimum Allele Frequency (MAF) > 0.1 is > 95% [5] therefore providing good power to select informative SNPs in each species separately and even more so in both species simultaneously. RAD sequence tags may be present or absent in specific individuals depending on the presence of the PstI restriction site providing large numbers of dominant markers; SNPs detected within the aligned tags provide additional co-dominant markers (Figure 1).

Out of a total of 200,712 SNPs declared with high confidence, 42,300 were simultaneously polymorphic in the two species while the remaining were fixed in one or the other. These 42,300 SNPs provide an average density of one SNP every 14 kbp in the Eucalyptus genome. These SNPs could immediately be used to select an evenly spaced set of SNPs for the development of a high density SNP genotyping platform. Taken together, the RAD tags plus the SNPs into them provide excellent marker density for applications such as Genomic Selection [6]. Besides the RAD method, Elshire et al. [7] recently described a straightforward method of genotyping-by-sequencing. Additionally the DArT complexity reduction protocol has also been streamlined based on NGS for a number of plant genomes including Eucalyptus (see Sansaloni et al. this meeting). All these NGS-based genotyping methods will cause a paradigm shift in our ability to carry out high density, high throughput and low-cost genotyping of large numbers of samples, unlocking incredible opportunities in forest tree genetics and breeding in the years to come.

Identification of five commercial *Eucalyptus* species by SCAR markers development

Karine Kettener1*, Aletéa Madacki1, Tânia Mara Bortolotto1, Shinitiro Oda2, Celso Luis Marino1
1Genetics Department, Biosciences Institute of Botucatu-SP, Brazil; 2Suzano Pulp and Paper, Brazil
E-mail: karinekettener@gmail.com

The genus *Eucalyptus* native to Australia, had some species introduced in Brazil between the nineteenth and early twentieth century and is currently planted in tropical and subtropical regions of the world. Currently, species of the genus have been highlighted as some of the most important in reforestation projects to provide wood for pulp, paper, energy and solid wood products. *Eucalyptus* breeders frequently face difficulties to identify closely related species and their hybrids that share common morphological traits, some of them expressed only later in the breeding cycle [1]. Molecular markers could be useful for early identification of species and hybrids. A strategy to identify species specific molecular markers is the use RAPD (Random Amplified Polymorphic DNA) combined with bulked segregant analysis [2]. We used RAPD markers and BSA to find putative species specific markers for five pure species of *Eucalyptus*: *E.* tereticornis, *E.* saligna, *E.* grandis, *E.* brassiana and *E.* urophylla. We tested 112 RAPD primers which generated 187 candidates polymorphic bands, of which 44 have proved reliable after validation carried out by genotyping individually all plants that composed the bulks. A good species-specific candidate RAPD marker was defined as being exclusive to one bulk, have a size between 300 bp and 2000 bp; provide easy visualization in agarose gel and display repeatability in independent assays. The best candidate bands were provided by the Operon primers: AD01, H03, H19, H20, K10, X06, W03, W05 and W07. As expected, although polymorphic between species, none of the RAPD markers were totally exclusive to one species and absent in the others. However by combining sets of two or more RAPD markers with contrasting frequencies among species it was possible to discriminate all species with high confidence. The most informative polymorphic RAPD amplicons were isolated, purified and cloned into pGEM®-T Easy Vector System I (Promega) and cloned into competent cells of strain DH5α®-ULTIMA™ (Lifetecnia, GibcoBRL) for subsequent sequencing and primers design. Based on the sequences obtained a set of SCAR markers was derived after carrying out a temperature gradient test ranging between 52°C and 69°C. The SCAR marker CXT1 allows the identification of *E.* tereticornis individuals with 80% efficiency. A combination of markers CAS1 and CAS2 or CAS1 and...
CBW 1 or CAS2 and CBW 1 allows identifying 90% of the E. saligna individuals. SCAR markers CAG1 combined with CHG1 can identify 100% of the E. grandis individuals; markers CAXG1 and CBW1 combined provide 90% identification of E. urophylla and CBW1 is a strong candidate to uniquely identify E. brasiiliana. These results indicate that the development of SCAR markers from intensive RAPD marker screening can be an inexpensive way to discriminate different species and possibly hybrids.

E-mail: medinacwb@hotmail.com
BMC Proceedings 2011, 5(Suppl 7):P47

Background: In last decades, the progress of molecular techniques, bioinformatics tools and genome analysis equipment allowed genomes to be sequenced and analyzed for several plants. For Eucalyptus, the combination of quantitative trait loci (QTL) mapping with genominc analyses, has allowed the identification and validation of a few genomic regions involved in growth and wood quality characteres. However, several forest companies still have difficulties to apply Marker Assisted Selection (MAS) at the operational level in their genetic improvement programs. Using as case study a Eucalyptus hybrid progeny, which had QTLs mapped for growth and wood quality characters, the present study compared the possible outcomes of traditional selection used in forest breeding programs, where individuals are classified by genetic values (eBLUP), with selection based only on superior QTL genotypes (MAS).

Methods: Genotype selection included 30 trees as the maximum number selected by both selection methods, an amount that corresponds to a 15% selection intensity in relation to the mapping population size used in this study. About 200 individuals of an interspecific hybrid progeny had 3 growth characters evaluated in the field and 5 wood quality characters predicted by Near Infra-Red Spectroscopy (NIRS). This progeny was genotyped with 76 microsatellite markers (SSR). An integrated genetic map was built at LOD 3 and 0.40 recombination fraction, composed by 65 SSR markers distributed in 12 linkage groups with total length of 1,365 cm and average distance among markers of 21 cm [1,2]. The genetic map built covered approximately 83% of the Eucalyptus genome estimated by Brondani et al. [3]. Due to the low density and large distance among markers obtained, QTL mapping was only carried out by single marker analysis using R, at p-values smaller than 0.01.

Results: Out of the 65 mapped loci, 10 of them (~15%) showed association with a total of 12 QTLs. 10 loci were associated with only one character and 2 loci with two different growth characters. Three characters showed association to only one QTL. The average volume growth of the 30 individuals selected by MAS was 55% lower than the average of the 30 best individuals selected by MAS to almost half of that of the 23 best individuals selected by eBLUP. For cellulose yield, the simultaneous selection for superior alleles at three QTL reduced the number of selected trees in the field trial from 29 to 2. The average value of MAS selected trees was 78% lower than the one of the 29 trees selected by eBLUP. In conclusion, for all traits evaluated, selection based on eBLUP was significantly more efficient than MAS. This result was expected, due firstly to the low marker density of our experiment and hence low power to detect all QTLs involved in the trait. Secondly due to the overestimated QTL effects that bias the real value of each QTL used in selection and finally to the fact that eBLUP based selection captures the final effect of all genes involved in trait expression, while MAS based on a few QTLs captures only a small portion of the variation. These results indicate that MAS for a few QTLs will hardly be useful as the sole selection criteria in forest breeding programs.

BMC Proceedings 2011, 5(Suppl 7):P48

Background: In Portugal, the private non-profit research institute owned by the Pulp & Paper Portucel Soporcel Group (http://www.raiz-ipf.pt), RAIZ. E. globulus genetic improvement program is managed in order to generate trees with increased economic value, through gains in forest productivity and wood properties. Molecular markers have been used for clonal identification and genetic diversity management in the program since 1990. Moreover, RAIZ has been engaged in a longer term genomics project aiming to identify quantitative trait loci (QTL) for wood properties. The ability to detect QTL depends on their adequate map location and the identification of the molecular variation behind them. This in turn is determined by linkage map quality, the choice of phenotypes and the precision of phenotyping. There are many reports in the literature on QTL detection for economically important traits in Eucalyptus, but very few present data on QTL verification (at the statistical and/or biological levels). We illustrate the importance of this issue for pulp yield related traits by comparing available results from QTL mapping studies in the literature with those obtained from a QTL detection and verification experiment pursued by RAIZ.

Methods: An F1, full-sib family with 361 progeny from an intraspecific E. globulus cross was planted in a field trial and phenotyped (at age 4½ years) for pulp yield using near infrared spectroscopy. Phenotypic data was adjusted for spatial variability and growth type and first-order separable autoregressive model. The NIR-PLSR spectra were recorded using a Bruker equipment (vector 22N model), and the calibration model to estimate pulp yield (RITK16) was constructed using partial least-squares regression as implemented in with the QUANT2 software. DNA extraction and microsatellite genotyping were carried out as described in [1,2]. Linkage analysis and map construction were performed on independent
male and female datasets using MAPMAKER/EXP® 3.0(3) under the $F_2$
backcross model. Framework maps with evenly distributed selected SSR
and gene markers were used for QTL detection (4-8). The selection of SSR
markers took into consideration the possibility to establish synteny
between available eucalypt maps in the literature. Interval Mapping and
Multiple Interval Mapping QTL detection results were compared with the
MultiQTL vs 2.6 software. QTL detection was repeated in data from 100
different simulations (using the R software), after adding to the original
phenotypes randomly selected values from a normal distribution with
mean zero and a standard deviation that accounted for the reference
essay error and the prediction error of the NIR calibration model.

Results: Many QTL for pulp yield related traits have been reported for
every eucalypt chromosome, in the literature. There is insufficient
mapping information to infer if these QTL were detected in similar
genomic locations. In 6 of the 11 eucalypt linkage groups (LG2, LG4, LG5,
LG6, LG9 and LG10), QTL for pulp yield related traits were detected in
different species (E. globulus, E. grandis x E. urophylla and/or E. nitens) (Figure 1). RAIZ reports two verified QTL for pulp yield, in an E. globulus
intraspecific cross, in linkage groups 3 and 11, detected in all simulations.
Although these results can reflect the polygenic nature of the trait (as
suggested by [9]) we cannot exclude the putative biases resulting from
current limitations of existing studies in terms of experimental designs,
phenotyping and/or data analysis.

Conclusions: QTL studies in some plant species have proved useful to
target genomic regions for subsequent genomics investigation [10].
Forest trees experience a variety of environmental conditions and it is
expected that some QTL will be age/environment specific and some will
be consistently detected over multiple growing seasons. In order to raise
the scope of inferences that can be drawn from QTL research in

Background: Prediction of breeding values (BV) using only genotypic information is the final goal of Genomic Selection (GS) [1]. Commonly, BV prediction from traditional BLUP analysis is the input for constructing GS prediction models, and GS predicted BVs are correlated with traditional BLUP BVs to estimate the accuracy of GS models. The use of GS in plant breeding depends on the accuracy of the GS models to predict the BVs. Therefore, better accuracy and less bias in traditional BLUP BVs should improve the final accuracy of GS predictions. Such improvements in GS predictions are not due to GS modeling itself, but rather to the reduced noise in the BLUP BV used as input. Improvements in BLUP BV can be obtained simply by correcting errors in the pedigree [2] or using more complex approaches, such as applying a realized relationship matrix (RRM) in the BLUP prediction as an alternative to the relationship matrix (A) based on expected values derived from the pedigree [3]. Misspecification of effects in BLUP models tends to produce upward bias in the BV estimates, which also impact GS accuracy [4]. In addition, not correcting with the additive-genetic relationship information in the GS prediction model leads to overestimates in accuracies due to inadequate accounting for confounding genetic relationships found in the training population [5]. The inflated accuracy cannot be exploited in future generations and should be guarded against. Our objective was to use real data to study the effect on the GS accuracy from 1) pedigree errors, 2) incorporation of the RRM in the BLUP analysis, 3) misspecification of non-additive effects in the BLUP analysis and 4) the effect of ignoring the additive-genetic relationship in the GS prediction model.

Methods: Height (HT) was measured in one field test containing 860 clonally propagated loblolly pine trees (~8 ramets per genotype) derived from 32 parents crossed in a circular mating design. The population was genotyped using the Illumina Infinium™ assay (Illumina, San Diego, CA) with 7,216 SNPs. A total of 3,938 SNPs were selected for use in GS based on frequency of polymorphism across genotypes, quality and reliability of the reads. SNP markers were used to estimate the RRM following a recently published method [3] where identity by descent is determined relative to a base population. RRM values were adjusted as recommended [6] to obtain less biased variance estimations. Based on the RRM, a new pedigree was constructed. Several BLUP models were fit in ASReml to study the following effects: Model 1: Additive + non-additive effects model – original pedigree Model 2: Additive + non-additive effects model – new pedigree (expected A matrix) Model 3: Additive model – new pedigree based (expected A matrix) Model 4: Additive model – RRM (observed A matrix)

Results and discussion: The RRM among 6475 full-sib pairs (Figure 1a) showed a normal distribution of relationship coefficients around the expected value. As expected, when the RRM was used to correct the original pedigree [3] the accuracy of the BLUP predictions increased from 0.80 to 0.85 (Table 1), and GS accuracy improved from 0.64 to 0.77 [4]. When the RRM was used directly, instead of the corrected pedigree accuracy of the BLUP, the BVs improved (Figure 1b). Improved BLUP BV estimates also resulted in the improvement of the accuracy of GS predictions from 0.58 to 0.60. The same results were obtained when the additive model was compared with the full model, indicating that misspecification of effects in the BLUP model will cause a decrease in the GS accuracy [5]. In addition, as shown [6] ignoring the additive-genetic relationship dramatically inflates GS accuracy from 0.58 to 0.87 and from 0.60 to 0.88 for Models 3 and 4 respectively.

Conclusions: To maximize the true accuracy of GS, it is recommended: 1) construct a RRM for the training population that should be used to correct the pedigree and to predict the BLUP BVs, 2) correct for non-additive effects if using a family related training population, and
3) deregress BVs prior to use as input for construction of GS prediction models.

Background: Eucalyptus camaldulensis is a widely planted tree species in India, because of its rapid growth and adaptability to dry regions. Genetic improvement through informed breeding of E. camaldulensis largely depends on availability of molecular markers, linkage maps and genome information. Microsatellite markers, also called as simple sequence repeat (SSR) markers have wide application due to their unique advantages over other marker systems. In Eucalyptus, SSR markers have been used in various breeding applications from DNA fingerprinting to QTL mapping [1,4]. Despite of their advantages, the major drawback is the time required for their development [6]. There are less than twenty five E. camaldulensis specific SSR markers available in the public database [5]. Although, there are large number of SSRs available in other Eucalyptus species [2,3], their species transferability in camaldulensis is questionable for practical use. Nevertheless, the existing camaldulensis specific SSRs are insufficient for developing linkage maps, QTL and comparative mapping studies. Besides, EST based markers are handicapped due to exclusion of introns, which sometimes lead to compromise on product sizing. Therefore we have modeled a novel strategy that targets highly conserved domain in the genic region using both publicly available ESTs as well as genome sequences.

Methods: Targeting conserved genic region: A set of publicly available E. globulus ESTs were assembled as unigenes using CAP3 algorithm and mined for repeat motifs using MISA program [http://pgrc.ipk-gatersleben.de/misa/]. The repeat rich unigenes were marked and mapped on the whole genome scaffolds of E. grandis. The sequence of mapped co-ordinates were extracted from EUCAGEN database [http://webup.ac.za/eucagen/] and further validated for repeat motifs and the presence of exons using MISA and GENSCAN [http://genes.mit.edu/genSCAN.html]. A total of 300 ± base paire were marked in the genic region of scaffolds flanking the repeat motifs and further primers were designed on the flanking region of repeat motifs using Primer3 tool [http://primer3.sourceforge.net/], following the appropriate parameters (Figure 1). The entire pipeline was automated and multi-threaded using a set of in-house Perl programs.

PCR, multiplexing and genotyping: We adopted an innovative two-tier polymerase chain reaction (PCR) system to reduce the cost 12 times on labeled oligo synthesis. The first PCR was performed with M13 tagged forward primer at 5’ end whereas the second PCR was performed with fluorescently labeled M13 as forward primer and SSR reverse primer. Multiplexing was carried out at post PCR stage. The first PCR consisted of template DNA (5 ng), primers (2 pM), 10X PCR buffer, dNTPs (1 µM), MgCl2 (1.5mM) and AmpliTaq Gold Taq DNA polymerase (0.25 U). The PCR profile consisted of denaturing the template DNA at 94°C for 5 min, followed by 35 cycles, each at 94°C for 30 sec, 50-65°C for 30 sec and 72°C for 1 min, followed by 72°C for 8 min. The first PCR products were resolved on 2% high resolution agarose. The second PCR consisted of template DNA (2 ng), 2 pM each of forward (labeled M13) and reverse (SSR) primer, 10X PCR buffer, dNTPs (1 µM), and 0.5U of Taq DNA polymerase. The PCR conditions remained same except reduced number of cycles to 20. The amplicons were resolved using ABI 3730 sequencer and each amplicon was manually validated for their allele size.

Results and conclusion: About 13,441 E. globulus ESTs and 13,380 camaldulensis EST/genomic sequences were collected from public database and mined for repeat motifs. A total of 2,330 repeat motifs were identified on 1873 ESTs of which, 1159 were di; 1128 tri and 43 were tetra repeats. There were more than 290 repeats found to be in compound form. The repeat containing ESTs were assembled to a total of 301 unigenes. These ESTs were mapped on E. grandis genome scaffolds.

Recent application developments in genomic research using the AdvanCE™ FS capillary electrophoresis platform
Julio Petersen*, Dylan Baker, Deepak Dibya, Pierre Varineau, Jeremy Kenseth
Advanced Analytical Technologies, INC
BMC Proceedings 2011, 5(Suppl 7):P50

Central to genomic research is the analysis of nucleic acids, which requires versatile, sensitive and high throughput technologies that can deliver accurate results in a short time. Reported herein are recent developments for sizing and/or quantifying nucleic acids (dsDNA and RNA) on a parallel capillary electrophoresis platform with LED-based fluorescence detection (AdvanCE™ FS system). This flexible multi-capillary platform has been employed for applications such as SSR, gDNA analysis, RNA analysis, quantification of next generation sequencing (NGS) libraries, and the separation and sizing of large cDNA from Populus spp. This poster will discuss recent validation of the platform for a subset of these applications in detail. The AdvanCE™ FS system successfully scored all SSR samples with resolution as low as 2 bp. Assessment of the quality/concentration of gDNA is also demonstrated with a new separation matrix, for separation of large DNA fragments. Separation and sizing of large cDNA was also demonstrated with good resolution and accuracy. A method for rapid and sensitive detection of total RNA concentration and quality will be discussed, as well as the sizing and quantification of NGS libraries. The AdvanCE™ FS platform offers rapid separation and ample resolution with excellent sensitivity and dynamic range, to benefit a variety of applications in genomic research.

BMC Proceedings 2011, 5(Suppl 7):P51
A total of 124 SSR positive scaffolds were identified and used for designing 230 primer pairs. Primers were standardized using gradient PCR at appropriate annealing temperatures. Of the 230 primers, 179 were successfully amplified and validated in *E. camaldulensis* resulting in 77.82% success. About 95% of the primers were amplified as single and clean product, indicating their locus specificity (Figure 2). These markers were validated in 4 *Eucalyptus* and 2 *Corymbia* species with multiple alleles ranging from 4 to 12. Surprisingly, 92% of cross species amplification was observed within the genus *Eucalyptus*, while only 21% in *Corymbia*. Higher species transferability in *Eucalyptus* genus shows the power of design as they originate from conserved domain. Further to validate these markers in *E. camaldulensis*, some of the selected primers

**Figure 1 (abstract P51)** Strategy summarizing the in silico development of orthologous SSRs.

**Figure 2 (abstract P51)** Electropherogram of multiplexed PCR products of primers IME3126 (black), IME3130 (blue) and IME3285 (green) in eight clones of *E. camaldulensis*. 
were successfully utilized for parentage analysis, confirmation of interspecific hybrid and genotyping of seedling seed orchard in *E. camaldulensis*. Unlike SSR markers developed from conventional in silico methods, orthologous SSRs resulted in very high success rate in Eucalyptus species due to targeted repeats in conserved domain. Our present strategy successfully demonstrated the power of orthologous SSR makers and its application in informed breeding in *E. camaldulensis*.

**PS2** Identification of SNPs in candidate genes related to water stress in *Eucalyptus*

Cíntia Helena Duarte Sagawa1, Leonardo Curi Martín1, Andréia Santoro1, Juliana Erika de Carvalho Teixeira1, Rinal do César de Paula1, Celso Luís Marino1

1Departamento de Genética, UNESP, Botucatu, São Paulo, 18618-970, Brazil; 2Departamento de Produção Vegetal, UNESP, Jactobat cabal, São Paulo, 14884-900, Brazil

E-mail: cintiasagawa@ibb.unesp.br

**Background:** Forest companies have occupied Northern and Northeastern of Brazil with plantations of Eucalyptus species; however, limitations on water supply are affecting the biomass production and reducing the yield significantly [1]. Tolerant plants develop defense mechanisms like hormone production of abscisic acid (ABA) and osmoprotector glycinin betain (GB) when submitted to drought conditions [2]. Identifying and studying genomic regions related to water stress tolerance are important for tree improvement programs. In this work, SNPs in candidate genes, 9-cis-epoxy-carotenoid dioxygenase (NCED) and choline monooxygenase (CMO), of A. CMO gene showed some unique genotypes for some species. Then, the genotyping of individuals by the allele-specific extension technique demonstrated to be efficient; moreover the SNPs primers designed can decrease costs and permit the genotyping of these mutations in large scale of contrasting populations to water deficit and in population studies. From the analysis of the DNA bulks, 50 AFLP primer combinations were tested from which 27 generated polymorphic bands between the bulks and just one primer combination was confirmed in all susceptible plants of the bulk by now. This fragment sequence will be compared and converted into PCR-based markers.

**PS3** Identification of genomic regions related to early flowering in *Eucalyptus*

Vanusa Socorro Leite1, Julio Cesar Santosotto1, Cintia Helena Duarte Sagawa1, Esteban Roberto Gonzalez2, Maria Gaziane Fagundes1, Shintiro Oda3, Celso Luis Marino1

1Departamento de Genética, UNESP, Botucatu, São Paulo, 18618-970, Brazil; 2Suzano Pelo e Celulose, Suzano, São Paulo, 08613-000, Brazil

E-mail: cintiasagawa@ibb.unesp.br

**Background:** The genus *Eucalyptus* is the most important planted tree to the Brazilian economy. Besides being a source of timber, its wood pulp is mostly used for papermaking. There is a considerable interest in its genetic improvement due to the economic importance of the gender to forestry companies. The time required to obtain ideal populations, after selective breeding, is a limiting factor of classical breeding in these species. However, the breeding program of Suzano Papel e Celulose company obtained a plant of *E. grandis* with the early flowering character, whose first flowering took place between 60 and 90 days. This plant was grown and its seeds were collected and germinated. Progeny segregated for early flowering after approximately 60 to 90 days.

**Materials and methods:** AFLP markers [1] combined with bulk segregant analysis method (BSA) [2] were used to search for specific DNA polymorphisms in the genome to produce markers which could identify the character at any stage of development. AFLP markers showed polymorphisms based on the distribution of restriction sites and differential amplification of the fragments. The methodology followed the routine protocols for the AFLP technique and BSA method. Contrasting bulks were prepared, one bulk with ten normal flowering plants and another with ten early flowering plants. DNA was extracted and digested using two restriction enzymes, a frequent cutting (MseI) and a rare cutting (EcoRI), followed by connection of the adapters.

**Results and conclusion:** The pre-amplification and selective amplification were performed to test 32 primer combinations, which were seen in 6% polyacrylamide gel stained with silver nitrate [3]. As a result, 13 primers amplified and showed polymorphic bands. These amplified fragments are candidates to be specific molecular markers but still need confirmation. Hence, new analyses are being conducted using DNA from each individual separately in order to verify its co-segregation with the early flowering phenotype. Moreover, confirming its effectiveness as a marker in these plants, new strategies will be adopted for validation, such as cloning, sequencing and the development of primers for testing in other populations of *Eucalyptus*. These results indicate the feasibility of using AFLP technique to detect polymorphisms, which might contribute to the improvement of the species.

BMC Proceedings 2011, 5(Suppl 7):P54

Background: Wider genome coverage and higher throughput genotyping methods have become increasingly important to meet the resolution and speed necessary for a variety of applications in genomics and molecular breeding of forest trees. Developed more than 10 years ago [1], the Diversity Arrays Technology (DArT) has experienced an increasing interest worldwide for it has efficiently satisfied the requirements of throughput, genome coverage and inter-specific transferability for over 40 different plant species to date, including Eucalyptus[2] and recently Pinus (Dione Alves-Freitas, this meeting). DArT is based on genome complexity reduction using restriction enzymes, followed by hybridization to microarrays to simultaneously assay hundreds to thousands of markers across a genome. Genome complexity reduction for genotyping has now been taken to another level when combined to next generation sequencing (NGS) technologies. Such a strategy has been used for rapid SNP discovery in different organisms [3], and proposed as a way to genotype with RAD (Restriction-associated DNA) sequencing [4] and recently Bowtie software (generated using Bowtie software) [5].

Methods: A segregating population of 89 individuals derived from the intra-specific cross BRASUZ1 x M4D31 was provided by Suzano company. Correct parentage of all individuals was certified by microsatellite genotyping. DNA samples of parents and progeny were processed for the conventional array-based DArT genotyping as described earlier [2] to generate marker data for comparative analysis with the NGS based DArT data. For the sequencing based DArT genotyping two complexity reduction methods optimized for several other plant species at DArT PL were used: PstI_ad/TaqI/HpaII_ad and PstI_ad/TaqI/HhaI_ad with TaqI restriction enzyme used to eliminate a subset of PstI –HpaII and PstI-HhaI fragments, respectively. PstI_ad is specific for barcode sequences. The filtered data were split into their respective target (individual) data using barcode splitting script. After producing various QC statistics and trimming of the barcode the sequences were aligned against the reference Eucalyptus grandis genome available in Phytozome. The output files from alignment (generated using Bowtie software) were processed using an analytical pipeline developed by DArT PL to produce “data score” tables and “SNP” tables. A linkage maps was constructed with JoinMap 3.0 [6] using the microarray-based DArT markers, DArT NGS markers, and 40 microsatellites of known map position as anchors. A parallel analysis exclusively meant to estimate the total number of potential SNPs within the short read tags was carried out using CLC genomic workbench v4.6 software [7] with a minimum read coverage of 6 and Kessl minimal variant frequency of 25%.

Results: The microarray-based DArT platform yielded 1,088 high quality markers of which 505 (46.4%) segregated in a 1:1 pseudo-testcross while the remaining 583 (53.6%) segregated 3:1. This relatively lower number of markers when compared to other Eucalyptus mapping populations was expected. Not only it is an intra-specific cross but also involves BRASUZ1, a known self (51) individual with a lower level of sequence heterozygosity. DArT genotyping using NGS technology yielded 2,835 polymorphic presence/absence markers, almost three-fold the number produced by the microarray platform. Of these, 2,449 markers mapped to the 11 chromosome scaffolds with an average of 222 markers per scaffold, while the remaining 386 markers fall out of the 11 scaffolds, potentially allowing the localization of a fraction of the still unassembled smaller genome scaffolds. In total, an integrated linkage map with 564 DArT markers, 1,930 DArT-NGS and 29 microsatellites was preliminarily built. Furthermore, from the 148 million reads generated (~10.5 Gb), 83.6 million (6.1 Gb) were successfully mapped on the Eucalyptus reference genome. Although a very large number of SNPs can be identified when all reads combined are mapped, only a fraction that displays sufficient coverage allows robust scoring at the individual level. Still, over 1,500 SNPs could be confidently genotyped providing a further advantage of adding co-dominant markers to the already large number of dominant markers obtained.

Conclusion: These initial results show that the combined use of DArT as a robust genome complexity reduction method with optimized barcoded NG sequencing protocol provides at least three fold more dominant markers than the conventional microarray-based DArT method and an additional set of co-dominant SNPs. We are now genotyping a much larger set of distinctly related individuals of a training population to be used for Genomic Selection (GS). The possibility of delivering large numbers of both dominant and co-dominant markers with the same platform will enable fitting dominance effect in predictive models therefore increasing the selection accuracy.

References
of selected individuals over several cycles of selection while at the same time maintain broad genetic base of the breeding populations. This is crucial to guarantee continuous genetic gains along the program. The establishment of efficient breeding strategies depends on methods and analytical tools. The assessment of genetic diversity with molecular markers of parents used in mating designs could aid optimizing the recombination phase. Microsatellites provide good information content and require small amounts of DNA and may be transferable between species of the same genus. In this study we evaluated the genetic diversity in a set of Eucalyptus parent trees and indicated those to be preferably crossed in a recombination process to potentially maximize variation in the offspring for individual selection of clones.

Materials and methods: A total of 20 genotypes were selected from 44 families obtained by crossing 24 parents in different types of hybridizations of populations of Eucalyptus grandis and E. urophylla. Genomic DNA was extracted from leaves and amplified with microsatellite developed during the Genylotpus project and previously used for Eucalyptus spp[1]. The amplifications were performed using the GeneAmp PCR System 9600 (Applied Biosystems) thermal cycler using the following amplification cycle: 96 °C for 2 min, 30 cycles at 94 °C for 1 min, specific primer annealing temperature for 1 min, 72 °C for 1 min and a final extension step at 72 °C for 7 min. Loci were amplified in single and duplex system. Tther to clustering were developed using the genetic distance matrix with the software Genes.

Results and conclusions: This study showed wide genetic diversity among the 20 genotypes under evaluation; all nine SSR loci analyzed were polymorphic, with a total of 77 alleles. The number of alleles per locus ranged from 5 (EMBRA 646) to 10 (Embora 645) averaging 9.1. The lowest value of polymorphism was obtained for marker EMBRA 915 (PIC = 0.39) and higher for the marker EMBRA 645 (PIC = 0.89). The expected heterozygosity ranged from 0.66 to 0.89, averaging 0.80. Based on genetic distances, the 20 genotypes were clustered into six distinct groups. The greatest genetic distance was observed between genotypes C022H (GIV) and M4232G (GVI), and the smallest among genotypes P023H (GII) and C407H (GIII). Group II clustered the largest number of genotypes (C386H, C407H, C053H, C051H, TC10H, P044H, VR3748H, VR3709, P4295H), consistent with the fact that these genotypes are considered to belong to the same heterotic group by the breeders. Based on the genetic distances, the following trees were selected to be preferentially crossed: M4232H, P4295H, P042G, VR3709H, C053H, C121H, C041H and C022H. It remains to be seen if the progenies derived from these crosses will in fact display a greater segregation and allow, as expected, effective selection of extreme phenotypes for wood and quality.

P56 Chloroplast SNP-marker as powerful tool for differentiation of Populus species in reliable poplar breeding and barcoding approaches
Hilke Schroeder1, Alex Hänken1, Matthias Flasch1
1Johann Heinrich von Thünen Institut (VTI), Institute for Forest Genetics, 22927 Grosshansdorf, Germany; 2University of Hamburg, Department of Wood Science, Wood Biology, 21031 Hamburg, Germany
E-mail: hilke.schroeder@vti.bund.de
BMC Proceedings 2011, 5(Suppl 7):P56

Background: the genus Populus is one of the world’s most important tree genera. High growth rates, particularly of some interspecies hybrids, and a broad range of applicability from wood and paper to energy production, led to their widespread cultivation in Europe and North America. For the use in SRCs (short rotation coppices), in particular interspecies-hybrids are well suited because of their superior growth and advanced resistance traits. However, Populus hybrids are often morphologically extreme variable and can show either more criteria of the one or the other parental species. Thus, species identification within the genus Populus using morphological characters can sometimes be difficult. Furthermore, systematically performed records during breeding or vegetative propagation of poplar hybrids and/or clones are not available to date. For breeding activities with the priority of registration of new high-efficiency clones, clear species identification is inevitably necessary. Therefore, we evaluate the usability of already published plant barcoding regions ("barcoding"; Barcode of Life [http://www.barcodeoflife.org/]) for their efficacy to differentiate seven often used poplar species. We present data on amplification success of the barcoding regions by using the already published primers. Moreover, novel primers were established in promising chloroplast regions to differentiate Populus species.

Methods: Twenty three published barcoding primer combinations were used for PCR amplification of coding and non-coding (intergenic spacers) regions. Additionally, 17 primer combinations have been newly designed taken advantage of the sequence of the Populus trichocarpa chloroplast genome. Obtained sequences were aligned and screened for presence of SNPs by using either the software SeqMan 7.1.0 from DNAStar (Lasergene, GATC Biotech, Konstanz, Germany) or Sequencher 4.9 (Gene Codes Corporation, Ann Arbor, USA). The sequences around the SNPs were checked for restriction sites using the software NEBcutter V2.0 from New England BioLabs Inc (Ipswich, USA).

Results: Twelve of the 23 used barcoding primer combinations and fifteen of the seventeen newly designed primer combinations resulted in PCR amplification products in all individuals for the seven species tested. Twenty four of these amplification products have been sequenced and checked for species-specific SNPs or indels. Three chloroplast regions containing species-specific SNPs using the original barcoding primers and within seven chloroplast regions species-specific SNPs or indels were identified when using the newly designed primers. A ranking, taking into account the percentage of variable sites for the ten chloroplast regions, reveals the first five places being occupied by intergenic spacers: trnH-psbA, psbK-psbI, trnG-psbK, ndhE-ndhG and rbcL-accD, followed by two coding regions: rps16 and rbcL again one intergenic spacer, rps2-psbC, and finally two coding regions rpoD and matk. Besides the usability of the identified SNPs and indels as contribution to the "barcoding of life" project, they should also be used to identify Populus species for breeding purposes. For an efficient application, rapid test methods without the need for sequencing or capillary electrophoresis facilities are required. Thus, all sequences with SNPs were checked for restriction sites for use as PCR-RFLPs. For five of the 21 identified SNPs suitable restriction enzymes were found. Thus, we can identify five of the seven used species by using PCR-RFLPs.

Discussion and conclusions: Altogether, the use of intergenic spacers seems to be more successful to differentiate closely related species as given within the genus Populus, because of the higher overall variability. Thus, the choice of suitable barcoding regions is obviously different for different groups of land plants. Our results support the recommendation of some authors of focussing the examinations of the plastid genome on the barcoding potential of the trnH-psbA spacer. We recommend focusing even more on intergenic spacers in general (for example trnM-psbK). And, therefore, our results also follow the idea of several authors in using multi-locus combinations, because differentiation of only seven species within the genus Populus requires three chloroplast regions. Our study clearly show that SNP markers combined with methods as PCR-RFLPs and length polymorphisms are convenient, easy to use, and necessary in most breeding programs – fast and of low cost for application in breeding projects.

P57 Genome-wide SNP discovery from a pooled sample of accessions of the biofuel plant Jatropha curcas based on whole-transcriptome Illumina resequencing
Orzemil B Silva-Junior1, Tatiana B Rosado2, Bruno G Laviola2, Manhua Pappas1, Georgios J Pappas Jr3, Dario Grattapaglia1

E-mail: orzemil@cegenagro.embrapa.br
BMC Proceedings 2011, 5(Suppl 7):P57

Background: Jatropha curcas(L) is an oil-rich, drought-tolerant perennial shrub of the Euphorbiaceae family widely dispersed throughout the world. Thought to be native to Central America, it has been the object of an increasing number of studies in recent years for it exhibits a number of
appealing attributes as a promising source of biodiesel. Although its undomesticated nature and preferential outcrossed mating system would suggest a high degree of genetic variation to be exploited in breeding, studies have shown limited genetic diversity in the existing germplasm collections [1]. In spite of the increased interest in this bioenergy plant, challenges still exist to turn this species into a genuine crop and improved varieties that consolidate desirable traits are not yet available, making JC large scale plantation an uncertain business [2]. Genomic studies to potentially assist JC breeding efforts have started in the last few years. JC is diploid (2n=22), with a haploid genome size estimated at 416 Mbp [3]. EST databases focusing on gene discovery were constructed [4] and a draft genome sequence was recently published covering 285 Mbp (~68%) of the genome in 120,586 contigs with 40,929 predicted gene models [5]. The focus of our work with JC is to provide effective tools to accelerate breeding through Genomic Selection (GS) [6] and to help assess the levels, organization and enrichment strategies of genetic diversity in germplasm banks and breeding populations. To this end we have started the development of SNP markers. Available EST databases built from single individual plants do not provide the necessary sequence diversity for SNP discovery. In this work we report on the discovery of a set of SNPs for JC derived from a pool of genetically diverse accessions using Illumina sequencing and a SNP selection pipeline recently described [7].

Methods: Genetic diversity data was used to select twelve JC accessions that maximized genetic diversity out of a germplasm collection currently serving as the foundation of a breeding program [1]. Total RNA of young expanding leaves was extracted from each individual plant and a pool of equimolar quantities of RNA was prepared. Two Illumina GAIIx single end lanes were sequenced following standard protocols. Raw reads were processed and aligned on the mapped reference genome using GSNAP [9]. GATK Unified Genotyper [10] was used to estimate the allele frequency in the pooled samples and to provide an accurate posterior probability of there being a segregating variant allele at each locus using a Bayesian genotype likelihood model. SNPs were then specifically selected to design Illumina Golden Gate Genotyping Technology (GGGT) assays based on an in silico estimated minor allele frequency MAF >0.10 and at least 60 bases available on each SNP flank with no additional SNPs following a procedure described earlier [7].

Results and discussion: The two lanes yielded a total of 74 million reads from which 66.5 million were filtered providing 11.8 Giga bases of high quality sequence. Upon mapping on the JC draft genome sequence 28,110 unigenes were sampled covering 22.1 Mbp of the 39.7 Mbp total unigene length, i.e. 56% of the transcribed portion currently predicted in the draft genome. From the 66.5 million reads, 60.8 were aligned on the genome with an average coverage of 152X of the unigene sampled. A large percentage of these reads (73%) were identical, derived either from abundant transcripts or more likely from amplification bias introduced by the PCR enrichment step during library preparation a standard occurrence in NGS [8]. After removing read amplification bias a total of 16.4 million de-replicated reads were aligned providing an average coverage of 26X of the sampled unigenes and a much more reliable substrate for SNP discovery. The distribution of percent coverage levels attained for each sampled gene was estimated (Figure 1). If a gene was completely covered by reads from the first base to the last at a depth >1X, then this gene was given a value of 100%. With no MAF and flanking sequences filtering a total of 18,225 SNPs were detected. When a MAF>0.10 was applied, 9,164 SNPs in 2,907 genes survived. When 60 bases with no SNPs on both flanks were required 1,574 high quality SNPs were recovered sampling 895 genes while 561 SNPs had coordinates not falling into any predicted gene model. These results corroborate the low level of sequence polymorphism in the breeding material and further highlight the need to widen the current germplasm base for successful breeding [1]. While a set of 768 high quality

Figure 1(abstract P57) Distribution of percent gene coverage. Distribution of percent gene coverage attained by the transcriptome sequencing at various coverage depth levels using dereplicated reads.
SNPs likely to show high conversion rate with the GGGT can now be developed, alternative genotype-by-sequencing technologies might provide wider genome coverage and thus assay a larger number of sequence polymorphisms.

BMC Proceedings 2011, 5(Suppl 7):PS8

Background: Over the last two decades, commercial plantations in Uruguay have increased exponentially, particularly those destined for pulp and paper industry. Although the about 700,000 ha of commercial plantations of Eucalyptus are a continuous source for the selection of elite genotypes, there is no national registration system for Eucalyptus clones in this country. The traditional procedure of clone identification accepted by the UPOV (International Union for the Protection of New Varieties of Plants) involves the evaluation of morphological descriptors such as leaf shape, bark texture, fruit shape, etc. [1]. The assessment of these characters varies from one observer to another, potentially leading to ambiguous results [2,3]. This restriction has led countries such as Brazil to include the use of microsatellite markers as additional descriptors, in their legislation. The hydroperviability and single inheritance of microsatellite markers provide a powerful clonal characterization system through fingerprinting. The identification of elite clones is nowadays one of the most widely used applications of molecular markers. This could generate a labeling system to follow the material traceability in companies with large-scale production of clonal nurseries. Proper identification makes new clones releasing easier and improves the management of seed orchards and controlled pollination breeding programs [4-6]. The aim of this study was to characterize 24 elite clones of several breeding programs in Uruguay, by the use of microsatellites. This was achieved by verifying the potential for discrimination of these molecular tools by assigning a specific molecular pattern of fingerprinting to each tested clone.

Methodology: Plant material was collected from 24 elite clones of Eucalyptus, provided by INIA Uruguay and Forestal Oriental. They were subdivided in 14 samples of E. grandis and 10 of E. dunnii. The tested clones were analyzed by PCR with 5 microsatellite loci using EMBRA 4, EMBRA 5, EMBRA 10, EMBRA 11 and EMBRA 16 markers under the same conditions as previously reported [7,8]. The molecular weight of the alleles was estimated with an automatic sequencer Macrogen Koera [https://www.macrogen.com/macrogen/macroseq]. The data obtained for each microsatellite was subjected to statistical assay to determine the following parameters: the probability of identity (PI), the paternity exclusion probability (Pe), the heterozygosity (He) and the observed heterozygosity (Ho). This analysis was performed with the software IDENTITY 1.0 [9].

Results and discussion: The generated data was sufficient to assign a specific profile for each tested clone. The five EMBRA markers amplified a total of 90 alleles and a maximum of 23 alleles for the EMBRA 11 marker. The minimum was found for the EMBRA 16 marker with 14 alleles. The remaining three markers showed 20, 18 and 15 alleles per locus. The probability of identity (PI) was 5.43 x10-9 and the paternity exclusion (Pe) 0.999. The expected heterozygosity (He) for all loci ranged from 0.894 to 0.958 while the observed heterozygosity (Ho) showed values ranging from a minimum of 0.471 to a maximum of 0.936 for every loci. A likelihood value of complete identity of 5.43 x10-9, guarantees the individual identity of each clone, as the probability of two being equal by chance is 1 in 184 million. A precise molecular pattern for each of the 24 genotypes could be assigned and the information produced is sufficiently robust to ensure the molecular traceability for each of these materials at the different stages of nursery production and/or field trials. However, the five markers derived from genomic sequence containing dinucleotide repeats. These markers, even when making a great discrimination, have reduced precision of genotyping, necessary for comparative multilocus profiling across laboratories or even at different times in the same equipment [10]. Considering a National System of Clones Registration, it proves necessary to increase the number of markers employed by including tetra and pentanucleotide markers to strengthen the precision and reproducibility among different laboratories. In addition, special emphasis should be laid on their selection, focusing on these microsatellites with high interspecies transferability. The testing of different species of Eucalyptus with the same molecular methodology and standardized procedures, will contribute to the registration of elite material and the protection of intellectual property.

Conclusions: The results show that using five microsatellite markers it is possible to discriminate among 24 clones and assigning a molecular fingerprint characteristic for each of them. The transferability of the five markers used is also verified, since they amplified both E. grandis and E. dunnii.

Selection of SSR markers for population studies in Eucalyptus globulus seed orchards

Diego Torres-Diniz1, Zohra Bennadji2, Laura Lima-Alano2, Natalia Nikichuk1, Fernando Resquín2, Gustavo Balmelli2
1 Forest Biotechnology Laboratory, INIA Tacuarembó, Uruguay; 2 Forestry Breeding Program, INIA Tacuarembó, Uruguay; 3 Universidad de la República, Montevideo, Uruguay
E-mail: dtorres@tb.inia.org.uy

Background: Eucalyptus globulus is a widely planted species in temperate regions of the world for pulpwood production. Its good characteristics for Kraft pulping in addition to a broad adaptability to different site conditions have led this species to be employed in commercial plantations and to be included in breeding programs [1]. Uruguay has approximately 300,000 hectares forested with E. globulus being the most cultivated species in the country and representing 45% of the total forested area. The main objectives of many Uruguayan breeding programs for E. globulus are the increase of volume per hectare, basic density and pulp yield. The strategies for genetic improvement used in many breeding programs in Uruguay require seed multiplication in seed orchards to obtain genetic gain [2]. In long-term breeding programs, the strict selection of reproductive populations restricts the number of genotypes involved in the final orchard, thus reducing genetic diversity and increasing the risk of depression through inbreeding in the following generations. The use of SSRs (simple sequence repeat) markers as selecting strategies of seed orchards in other species such as Eucalyptus dunnii, has proved to be an excellent tool to reduce inbreeding [3,4]. The transferability of SSR markers across Eucalyptus species has been widely studied [5-8]. The aim of this work was to select highly polymorphic SSR markers of E. globulus to assist breeding programs.

Methodology: Eighteen E. globulus samples were collected from the breeding program of the National Agricultural Research Institute of Uruguay DNA was extracted with CTAB 2X buffer [9]. Eight SSR markers, previously reported for E. grandis and E. urophylla were used: EMBRA 8, EMBRA 11, EMBRA 18, EMBRA 32, EMBRA 47, EMBRA 51, EMBRA 58 and EMBRA 155 [6,7]. The annealing temperature was specifically adjusted for E. globulus using a temperature gradient of 52°C – 56°C. The other reaction parameters did not differ from those previously reported. The results were visualized in polyacrylamide gels 8% under denaturing conditions at 80 W constant power over 3h 30min and were stained with silver nitrate. The estimated molecular weight of the alleles was made by comparison with a ladder. The matrix information was analyzed with the software Identity v 1.0 [10] and the following parameters were calculated: alleles number per loci, expected heterozygosity (He), observed heterozygosity (Ho), identity probability (Pi) and paternity exclusion probability (Pe).

Results and conclusion: From the eight tested markers, EMBRA 8, EMBRA 18 and EMBRA 13 did not amplify at any of the tested temperatures. EMBRA 11 and EMBRA 47 showed good amplification at 52°C of annealing. The rest of the primers worked optimally in the conditions previously described for E. grandis and E. urophylla[7]. The five SSRs markers amplified a total of 42 alleles. With a maximum of 14 alleles for EMBRA 11, 9 alleles for the markers EMBRA 47 and EMBRA 58 and 5 alleles for the markers EMBRA 18 and EMBRA 155. The range of heterozygosity expected for all the loci ranged from 0.64 to 0.88. However, the observed heterozygosity showed values of 0.1 to 0.9. With this information the probability of identity (IP) was 17 x 10-3 and the paternity exclusion probability was 0.99. The considerable number of SSR markers currently published (6-8) confirm how necessary the availability of these tools is to carry out precise population analyses. The five identified markers turned out to be promising candidates to be used in E. globulus seed orchards population studies.

BMC Proceedings 2011, 5(Suppl 7):P60

Genetic merit can be considered the finite sum of thousands of allelic effects, each physically located at some place on the genome, whose transmission can be traced through molecular markers. Traditionally, best linear unbiased prediction (BLUP) of breeding values relies on average additive genetic covariances (the numerator relationship matrix A) derived from pedigrees to utilize information from relatives. For example, all pairs of full-sib offspring of a cross are assumed to share 50% of alleles in common. Such assumptions ignore variation in Mendelian segregation of alleles among progeny within family. With advances in marker genotyping technology and reduction in genotyping cost, it is now feasible to estimate genetic covariances from markers. Linear mixed models that utilize realized genomic relationship matrices could predict genomic estimated breeding values (GEBV) more accurately than those that use expected average genetic covariances derived from pedigrees. Dense markers can be used to trace identity by descent probabilities at each locus, and those probabilities used to construct an incidence matrix. The incidence matrix is used to estimate the genomic relationship matrix (G), which is used in place of the A matrix in solving the mixed model equations. This may allow more accurate estimation of individual breeding values than the traditional model based on average genetic covariances.

We estimated realized genetic covariances between cloned progeny of a P. taeda population. There were 165 cloned progeny derived from nine
full-sib families. The realized genomic relationships were based on a set of 3,461 biallelic SNP markers. We used the following linear mixed model

\[ y = Xb + Zu + e \]

To estimate GEBV. In the model, \( X \) and \( Z \) are incidence matrices, \( b \) is the vector of fixed mean, \( u \) is the vector of additive genetic effects that correspond to allelic substitution effects for each marker with \( \text{Var}(u) = \text{I} \sigma_a^2 \), where \( \sigma_a^2 \) is the marker variance and \( I \) is the identity matrix. The term \( e \) is the vector of residuals. The dimension of \( Z \) is the number of individuals (n) by the number of loci (m). The regression method used to construct our matrix did not require allele frequencies; instead, the inverse of the G matrix was generated by regressing \( Z^2 \) as a dependent variable on the \( A \) matrix as the independent variable. Therefore, the expected value of \( G \) is \( A + \text{const} \) matrix. Different cross-validation methods were used to test performance of the \( G \) matrix. Clones were divided into a training group with both marker and phenotypic information and a validation group for which only marker genotypes were used. In one scenario ~90% of the clones (148) were sampled for training, either randomly selecting within each of the nine families or at random without family consideration. The remaining ~10% were used for validation (17 clones). In the second scenario, ~50% of clones (84) were sampled either within family or randomly from the whole population for training, and the remaining ~50% were used for validation (81 clones). The model parameters estimated in the training set were used to predict GEBV in the validation set. For each scenario, six independent samplings were carried out. The mean correlation between the GEBV based on \( G\text{-BLUP} \) and breeding values based on \( A\text{-BLUP} \) were determined for each scenario, along with the accuracy of the BLUP predictions for both \( G \) and \( A \) based models. The mean correlation varied from 0.37 to 0.61 across the four validation methods. The accuracies of the predictions for any validation scenario were always higher for \( G\text{-BLUP} \) (range of 0.63 to 0.75) than \( A\text{-BLUP} \) (0.60 to 0.62), which is related to the smaller standard error of the predicted \( G\text{-BLUP} \) for the validation clones (17 or 81) under the different scenarios. Estimating realized genetic covariances based on the genotypes of biallelic markers and incorporating those estimates into \( G\text{-BLUP} \) helps to more accurately characterize Mendelian segregation of alleles, and could allow more accurate selection within family. Such a method would increase genetic gains in forest tree breeding. The major impact would be on reducing the need for expensive field testing, but it may also be possible to shorten the breeding cycle and thus increase genetic gain per unit time and cost. The impact of genomic selection applications in forest tree breeding may be greater than for other crop or animal species, because of the biology of trees and their much longer breeding cycles.

**Imputing missing genotypes: effects of methods and patterns of data**

Funda Ogtu1, Fikret Tak2, Steven McKeand2, Ross Whetten2*

1Cooperative Tree Improvement Program Department of Forestry and Environmental Resources, North Carolina State University Raleigh, NC, USA; 2Cooperative Tree Improvement Program Department of Forestry and Environmental Resources, North Carolina State University Raleigh, NC, USA

BMC Proceedings 2011, 5(Suppl 7):P61

Costs of high-throughput genotyping have decreased to the point where it appears economically feasible to use molecular genetic marker information in applied breeding programs. Some practical questions remain to be addressed about how best to deal with missing data in the resulting genotype datasets, to minimize the impact of the missing data on the accuracy of breeding value prediction. Data can be missing for two reasons – first, genotyping assay failure is likely for at least some loci in some samples; and second, it may prove economically desirable to invest more resources for high-density genotyping of a few individuals and fewer resources for lower-density genotyping of many individuals [1]. The proportion of missing genotypes may range from less than one percent due to genotyping assay failure, to over 80% if a selective genotyping strategy is used. Many methods for predicting genetic merit of trees using marker genotypic data require complete genotype information for mathematical reasons. It is therefore important to use efficient statistical methods to accurately impute missing genotypes. In species with complete reference genome sequences available, the map order of markers and linkage disequilibrium (LD) information can be used to guide imputation of missing genotypes. Completely sequenced reference genomes are available for only two forest tree species, so these methods are not suitable for most forest trees. Gengler et al. [2] describe a method to impute missing genotypes using mixed linear models and BLUP. We determined the effect on accuracy of BLUP estimated breeding values of imputation with different levels (10%, 20%, 40%, 60% and 80%) of missing genotypes. Analyses were conducted both with empirical data (3461 SNP markers in a cloned loblolly pine population of 165 genotypes) and simulated data, using missing data created by random sampling (some loci missing in all individuals) or by structured sampling (all loci missing in some individuals). Simulations were used to examine the effect of family and progeny size, mating design, proportion of missing genotypes, genotyping strategy and the method for imputation on the accuracy of breeding values. Imputed genotypes were obtained using the numerator relationship matrix (the \( A \) matrix) and solving the mixed model equations of

\[ y = Xb + Mu + e \]

where \( y \) is the vector of gene content predictions, \( X \) is the design matrix (vector of 1s) for the mean, \( M \) is the design matrix connecting trees to the gene content vector \( u \), and \( e \) is the individual error vector. The solutions of mixed model equations produce predicted SNP genotypes for trees with missing genotypes. The solutions would be continuous, centered on 1 because the gene content values are 0, 1 or 2.

Imputation of missing genotypes in empirical data from an unbalanced mating design with family sizes ranging from 1 to 35 was more powerful for data with structured missing genotypes at all levels of missing data than for data with random missing genotypes with same proportions of missing data. The accuracy of imputation for 10% and 80% missing genotypes ranged between 0.96 to 0.23 and 0.96 to 0.16 for structured and random missing genotypes in the data, respectively. As the proportion of missing genotypes increased in the data, the power of imputation decreased. With simulation, we found that the imputation was less affected by the distribution of missing genotypes in a balanced mating design with families of equal size. The accuracy of imputation ranged between 0.97 to 0.75 for the 10% and 80% missing genotypes in the data, respectively.

Phase change in higher plants, from juvenile to mature, affects the reproductive competence, morphology and growth rate, as well as the regenerative potential of tissue explants. However, in conifers these changes can be achieved before the onset of flowering and at the beginning of the seed production. Early maturation changes in conifers are very obvious, severe and overall irreversible [1], and are characterized by lost of morphogenetic capacity. This may affect clonal multiplication programs and genetic manipulation, due mainly to the decline in adventitious rooting capacity which is the most marked maturation and aging effect. Despite the serious effects of these processes, little is known about their basic regulation in forest clonal propagation programs. The latest researches regarding this subject are related to auxins changes during maturation [2], epigenetic variations during phase-change, like DNA methylation [3], and proteomic changes during needle maturation [4].

However, in conifers these changes can be achieved before the onset of flowering and at the beginning of the seed production. Early maturation changes in conifers are very obvious, severe and overall irreversible [1], and are characterized by lost of morphogenetic capacity. This may affect clonal multiplication programs and genetic manipulation, due mainly to the decline in adventitious rooting capacity which is the most marked maturation and aging effect. Despite the serious effects of these processes, little is known about their basic regulation in forest clonal propagation programs. The latest researches regarding this subject are related to auxins changes during maturation [2], epigenetic variations during phase-change, like DNA methylation [3], and proteomic changes during needle maturation [4].
This work has been performed to gain deeper insight into the genetic mechanisms that regulates the loss of morphogenetic capacity with the aging process in P. radiata. 

P. radiata ortets of different age were brought from La Posada nursery at BioBio region, Chile. Needles were collected in August, frozen in liquid nitrogen and stored at -80°C until its RNA extraction. RNA was isolated from 100 mg of frozen tissue according to Chang [5], the RNA extracts were purified with RNeasy Clean up and treated with RNase-free DNase (both from QIAGEN). Gene expression analysis was done by a reverse dot blot hybridization technique by comparing the transcription levels of 174 genes in 1, 3 and 5 years old ortets using the methodology described by Valledor et al. [4]. The 174 genes analyzed were classified into categories being the most important: Chloroplast and photosynthesis, protein translation folding, modification and degradation and proteins involved in transcription and DNA replication. Gene expression was quantified as signal intensity using the Gel Pro-analyzer 3.1. The values were normalized dividing every spot intensity by the average of the intensity of each membrane.

From the 174 studied sequences only 56 were differentially expressed among ortets of different ages. From the 56 genes differentially expressed, 27 showed a clear variation tendency with age, from which 21 were down-regulated and 6 were up-regulated, reflecting a higher number of active pathways in the younger ortets. GBBS1, PPI-phosphofructokinase and α-L-fucosidase (Figure 1) genes are related with carbohydrates and carbon metabolism that were affected by the ortet age; all were down-regulated with the increasing age, showing a significantly lower level of transcription in ortets of 5 years old. Both PPI-phosphofructokinase and α-L-fucosidase have been correlated to a higher level of expression in younger and metabolically active tissues. GBBS1, PPI-phosphofructokinase and α-L-fucosidase have been correlated to a higher level of expression in younger and metabolically active tissues. Specifically the Arabidopsis thaliana fucosidase (AtFXG1) has shown a higher expression level in younger leaves than in the older ones, and it has been proposed that it has a role as a growth regulator. The previous results are consistent with the higher expression level in RUBISCO activase (figure 1) in the younger ortets (1 and 3 year old), which in turn agree with different studies, indicating that photosynthesis is reduced with increasing age of shrubs and trees [7] and higher in the younger ones. 

Transcription regulated protein family were mainly over expressed in 1 year old ortets. It is the case of the chromosome condensation gene regulator (RCCI) (figure 1), which inhibit the chromosome condensation until G2 phase of the cell cycle and is required for the formation of the mitotic spindle [7]. This result indicates that 1 year old ortets are more transcriptionally active. Likewise, proteins like Putative valyl-tRNA synthase and T-complex polypeptide protein like (TCP-1) (figure 1), involved in processes of protein modification and translation, were up-regulated in 1 year old ortets, indicating that juvenile plants are more active at protein synthesis and modification level. In contrast 5 year old ortets presented a down-regulation in these genes expression. Additionally, in 5 year old radiata pines genes like histidine-rich glycoproteins (figure 1) were up-regulated, this type of protein have been found to be a component of the cell wall, like histidine-rich extensin in Zea mays [9], this is consistent with the increase in cell wall synthesis in older plants.

Thus, this work has provided an initial insight of the pathways and mechanisms that may be involved in the loss of morphogenetic capacity caused by aging in P. radiata ortets. Juvenile ortets showed higher expression in proteins related with transcription activators, photosynthesis and carbon and carbohydrate metabolism, while older P. radiata ortets showed a down-regulation in the same genes and a increase in genes related to cell wall synthesis, indicating that these might be candidates genes to be markers of the aging and maturation process, results that will be complemented and validated with qRT-PCR and proteome studies.

BMC Proceedings 2011, 5(Suppl 7):P63

Background: R2R3-MYB transcription factors are regulatory genes that have been linked to key aspects of plant development and secondary metabolism. They have been implicated in the transcriptional control of phenylpropanoid, and flavonoid metabolic pathways in model plant systems. However, in trees, knowledge is still limited about the role of R2R3-MYBs in such processes. Microarray transcript profiles (9k custom cDNA array) obtained from comparison between wild type and transgenic spruces that constitutively overexpressed Pinus taeda MYB1, MYB8 [1], and MYB14 [2] identified putative targets in flavonoid and phenylpropanoid metabolism. Cross-comparison of these data sets identified 70 sequences that were common to the three transgenic backgrounds: interestingly, 66 of these 70 sequences were co-expressed between PmMYB1 and PmMYB8 transgenics but produced opposite profiles with PmMYB14 transgenics. Pairwise comparisons between these transgenic data sets identified 121 additional sequences showing opposing profiles. Predicted annotations and KEGG classification showed that many of the sequences were linked to the metabolism of amino acids and carbohydrates as well as flavonoids, phenylpropanoids, and terpenoids. It was hypothesized that MYB1/MYB8 and MYB14 may be part of competing transcriptional networks for the regulation of metabolism and secondary metabolism. The opposite transcriptional responses might also support structural or defensive oriented response, respectively.

Material and methods: A qPCR based experimental approach was used to test these hypotheses by evaluating transcript profile of the negatively co-expressed sequences together with MYB1, MYB8 and MYB14. Transcript levels were monitored during a diurnal cycle in three year-old wild type spruces, based on the fact that some genes associated to phenylpropanoid metabolism [3] and stress [4] were reported to follow a diurnal transcript variation. Our analysis also included a set of 10 additional MYBs putatively linked to secondary cell wall deposition [1] and stress oriented response [2]. A Spearman correlation rank test was used to estimate significant correlation (adjusted P val ≤ 0.01, FDR 1%) between MYB transcript profiles and selected co-expressed sequences. A functional assay system developed in embryogenic spruce cells was used to screen for possible interactions between transcription factors and promoters of putative target genes.

Results: Among the co-expressed sequences tested, five sequences coding for 4CL, DH52, OMT1, SMT4, and a Lipase thioesterase displayed transcript profile that positively correlated with those of PgMYB1, PgMYB8 but negatively with those of PgMYB14 and PgMYB15, the closest homologue of PgMYB14 [2]. Interestingly, these oppositions were observed in secondary xylem differentiating tissues but not in bark/phloem. Significant correlations were also observed between the co-expressed sequences tested and the others MYBs. A separate analysis of large scale expression profiles for spruce transcription factors gave some additional evidences that these putative competing MYB networks may be tissue-preferential. Transient expression results obtained with our functional assay system further suggested interactions between these MYBs and some of their proposed targets. More extensive testing is in working trees.

Conclusions: The results of the present study strongly suggest that putative MYB networks may compete to allow rapid metabolic switch within wood forming tissue in order to direct metabolic flux towards specific aspects of primary and secondary metabolism for structural, or defensive-oriented response.

P64 Expression of auxin carrier genes during adventitious rooting in Eucalyptus globulus
Arthur Fett-Neto1, Marcia De Almeida, Carolina Ruedell
Gabriela Pereira Center for Biotechnology, Federal University of Rio Grande do Sul, Porto Alegre, RS, Brazil
E-mail: fettneto@cbiot.ufrgs.br
BMC Proceedings 2011, 5(Suppl 7):P64

Background: Eucalyptus globulus and its hybrids are important for the cellulose and paper industry, mainly due to their relatively low lignin content. However, rooting of cuttings of this species is often recalcitrant and exogenous auxin application is necessary for adventitious root development. Auxin plays a central role in rooting capacity, which is particularly affected by its endogenous content and transport rate. The shoot apex is a major source of endogenous auxin, which is mainly transported by both influx (AUX1) and efflux (PIN) carriers in a specific basipetal active transport through the vascular parenchyma in stems. As part of a larger study to investigate the causes of low rooting in E. globulus microcuttings without exogenous auxin, we evaluated the expression profiles of AUX1 and PIN1 during the process of adventitious rooting using qPCR.

Material and methods: E. globulus in vitro tip microcuttings obtained from 14 week-old seedlings were submitted to a culture system consisting of a two-step protocol: an initial step of induction, which lasted 96 h (induction medium composition: 0.3x MS salt concentration, 0.4 mg l−1 thiamine HCl, 100 mg l−1 inositol, zero (control) or 10 mg l−1 indolyl-butyl acid (IBA – root promoting auxin), equivalent to 49.3 μM, 30 g l−1 sucrose and 6 g l−1 agar, followed by a formation step (same composition of induction medium, but devoid of auxin and supplemented with 1 g l−1 activated charcoal). The expression analysis of the selected genes was monitored along the rooting process and the harvest of microcuttings for RNA extraction in Pinus radiata D. Don. The transcript analysis was done at 6, 12, 24, 48 and 96 h of exposure to induction medium and 24 and 48 h after transfer to formation medium (formation step), for both treatments (with and without auxin in the first step). For the formation step harvest, the microcuttings remained for 96 h in the induction medium before transfer to formation medium. Total RNA was extracted, and the first strand cDNA synthesis was performed for all of the samples starting from about 500 ng total RNA, using oligo-dT primers and
reverse transcriptase M-MLV (Invitrogen) in a final volume of 20 μL. The final cDNA products were diluted 50-fold in RNase-free distilled water prior to use in qPCR. This was carried out using specific primers for Arabidopsis thaliana orthologue genes in eucalypt and both Histone H2B (H2B) and Alpha-Tubulin (TU) genes were used as references [1]. The data were analysed with the comparative Ct method [2].

Results and conclusion: The gene encoding the auxin influx carrier (AUX1) did not show differences in expression profile between treatments (with and without exogenous auxin), suggesting that AUX1 is not critical to the process of adventitious rooting promoted by exogenous auxins in microcuttings. This would be in line with the fact that the rate of endogenous auxin transport is probably not limiting under exogenous auxin supply. The auxin efflux carrier gene encoding PIN1 showed an expression increase during the first 24 hours of the induction step in microcuttings exposed to exogenous auxin when compared with the control treatment (without exogenous auxin supply). This result seems to indicate a requirement of PIN1 to redistribute and perhaps concentrate auxin, possibly IBA-derived IAA (indolyl-3-acetic acid), in specific areas of the base of microcuttings, in order to allow root development. Although IBA is a natural auxin recognized as an IAA precursor, its use as exogenous auxin instead of IAA, a common practice in clonal propagation by cuttings, may have also involved the expression of other sets of recently described IBA-specific transporters [3]. In conclusion, despite the unusual exogenous auxin entrance pathway into the microcutting compared to the endogenous auxin fluxes, PIN1 likely takes part in the process of auxin concentration required to program founder cells involved in the establishment of new root meristems.

sequenced by ABI3100 Genetic Analyzer (Applied Biosystems). SCAR derived sequences were compared among themselves and with the eucalypt genome (Phytozome v7.0 database - http://www.phytozome.net/) using BLAST. The genomic region identified was analyzed by FGENESH tool (Softberry, Inc. – http://www.softberry.com) to find predicted genes in the region. Predicted genes were translated by EXPASY translate tool (http://expasy.org), and the protein analyzed by PFAM database (http://pfam.sanger.ac.uk) for domain identification.

Results: Chi-square analysis confirmed Mendelian segregation of 3 normal: 1 anomalous seedlings in the tested progeny. The data indicate that the anomaly is a monogenic character that manifests when the deleterious recessive allele is in homoyzogosity. Among the random primers tested only one showed polymorphism with the segregation pattern. This marker appears in all abnormal and in 31% of normal individuals. The RAPD marker was converted into a SCAR marker and its segregation pattern confirmed. All abnormal individuals and 22.2% of normal individuals showed the marker. Sequencing of the SCAR marker was done to identify the possible genomic region where it is linked and detected a polymorphism of two base pair between abnormal (mutant) and normal individuals. Our in silico analysis showed the polymorphism in an intergenic region, localized between two protein-coding with a Bet v1-type domain belonging to the PR10 family (Pathogenesis-related protein 10). In general, this is associated with plant defense function in response to biotic and abiotic stresses (3-5). However, there are reports that PR10 may have important roles in biological processes (4,5).

Conclusions: According to our results, we propose that the anomalous character might be caused by a major effect gene. The marker found is correlated with the recessive; therefore, normal individuals with the marker are likely heterozygous. The polymorphism detected in the SCAR sequence, suggests that the mutation might be related to the two base substitution observed. However, at this point, it is unclear whether these base substitutions are involved affecting close genes (such as the identified PR10 proteins) or any other unknown genomic region. Expression analysis of the PR10-coding genes might provide clues to answer this biological question.

P67 NAC regulation of embryo development in conifers

Emma Larsson , Folke Sibton, Jens Sundstrom, Sara von Arnold Swedish University of Agricultural Sciences, Department of Plant Biology and Forest Genetics, PO. Box 7080, 75007 Uppsala, Sweden
E-mail: emma.larsson@svu.slu.se

Background: In most gymnosperms the cotyledons develop as a crown surrounding the incipient shoot apical meristem (SAM), which maintains the radial symmetry of the plant throughout embryogenesis. This is in contrast to the Arabidopsis embryo in which a symmetry-breaking event (from radial to bilateral symmetry) is associated with the emergence of the SAM and the two cotyledons [1]. We have previously shown that the differentiation of cotyledons and the establishment of the SAM and the root apical meristem (RAM) in somatic embryos of Norway spruce (Picea abies) is dependent on polar auxin transport (PAT) [2]. In Arabidopsis PAT restricts the expression of several genes belonging to the large plant specific NAC family of transcription factors [3-5], which in turn induce developmental processes involved in shoot boost and root formation. Members of the NAC family have a conserved DNA-binding domain in the N-terminal region known as the NAC domain, and a more diverse domain in the C-terminal region, proposed to be responsible for the transcription activation capacity of the protein [6]. Despite the diversity of the NAC gene family, and the importance of NAC proteins in fundamental processes, no NAC genes have to our knowledge been characterized in conifers.

Methods: Phylogenetic analyses of NAC domain containing genes from Picea glauca, Arabidopsis thaliana, Medicago truncatula and Physcomitrella patens were performed using PAUP* and MrBayes. Full-length cDNAs of two NAC genes were isolated from maturing somatic embryos of Norway spruce and cloned using standard protocols. The promoters were amplified using the Genome Walker™ kit (Clontech). The motif discovery tool MEME was used to find conserved motifs in the C-terminal regions and in the promoters of the NAC sequences from different species. The expression pattern of the two isolated NAC genes was analyzed in Norway spruce somatic embryos using quantitative real-time PCR. Their expression was also analyzed in embryos that had been treated with the PAT inhibitor NPA as described earlier [2]. Promoter::GUS fusions were inserted into embryogenic cultures of Norway spruce using Agrobacterium mediated transformation.

Results and discussion: We identified several different NAC sequences from white spruce in GenBank and deployed them to different sub-clades within the NAC gene family. Two full-length cDNAs (gene 1 and gene 2) were cloned from Norway spruce. Both genes have elements in their promoter region which are significant for specific NAC genes. Furthermore, gene 1 harbors previously characterized motifs that have been shown to have functional importance in NAC genes in Arabidopsis.

P66 Apparent coordination of isocitrate dehydrogenase and glutamate decarboxylase expression in early stages of tree development

BMC Proceedings 2011, 5(Suppl 7):P66

The biosynthesis of 2-oxoglutarate and glutamate are key steps in the biosynthesis of nitrogen compounds and plant development. The reaction catalyzed by cytosolic isoenzyme of NADP+-linked isocitrate dehydrogenase (IDH) is also considered as the main route in the production of 2-oxoglutarate. According to its expression pattern during development, IDH is also involved in other, yet unknown, processes [1,2]. In addition to the importance of glutamate in the biosynthesis of nitrogen compounds, glutamate also serves as precursor of GABA, a molecule that is currently considered as a signal in higher plants. GABA is produced by the action of glutamate decarboxylase (GAD), a cytosolic enzyme that is regulated by Ca2+/calmodulin and pH. In contrast to IDH, that it is encoded by just one gene in most of plant genomes [2], GAD is encoded by a small family of nuclear genes [3]. The expression of IDH and GAD has been investigated during the differentiation of hypocotyl and stem in tree species. Our results indicate a coordination of the expression of IDH and GAD in developmental processes suggesting a role for 2-oxoglutarate supply and GABA synthesis during early stages of organ differentiation in trees.

References
The relative expression of gene 1 increased as early embryos differentiated, and remained at a high level until separated cotyledons were clearly visible. However, the up-regulation was blocked in embryos that formed fused cotyledons and lacked distinct SAM and RAM after being treated with NPA. The relative expression of gene 2 was high in proembryogenic masses and early differentiating embryos but decreased as the embryos developed and matured. Interestingly the down-regulation occurred at about the same time as the cotyledons were delineated. The expression of gene 2 was not dependent on PAT. Spatial expression analysis using promoter::GUS fusions revealed that the spruce genes have specific expression patterns, distinct from the expression patterns of their most closely related Arabidopsis counterparts.

Conclusion: Taken together, our results show that NAC genes with distinct signature motifs existed before the separation of angiosperms and gymnosperms approximately 300 million years ago. However, through evolution the expression of closely related genes has diversified leading to induction of distinct developmental programs in angiosperms and gymnosperms.

References

Background: Bolting is regarded as the initiation of reproduction stage in the growth and development of an Arabidopsis plant, when a set of floral integrator genes activate the expression of floral meristem identity genes LFY and AP1 to initiate flowering transition[1,2]. However, how the expression of key genes, such as AP1, responds of diverse signals during flower development remains largely unknown. Here we have obtained an inbred line exhibiting an abnormal stem/inflorescence and flower development.

Methods: The morphological variations were carefully observed visually or with a Zeiss SteREO Discovery V8 stereomicroscope. Hybridization of GeneChip arrays was done in an Affymetrix Hybridization Oven 640 following the manufacturer’s protocol (Affymetrix) and expression levels in seedlings and flower buds were calculated from Affymetrix intensity data. Real-time PCR was performed on an ABI 7500 Real-Time PCR System (Applied Biosystems, Shanghai, China) with SYBR GreenPCR Master Mix (Applied Biosystems) as the fluorescence source.

Results: The inbred line exhibits a flower phenotype similar to the ap1, such as homeotic conversion of sepals (first whorl) to leaf-like, petals often absent (second whorl) and complete flower-to-inflorescence conversions (Figure 1, B). However flower meristem was replaced by emerging inflorescence meristems thus leading to a stacked stem/inflorescences before final flowering (Figure 1, D). Position and degree of stacked stem/inflorescences are varied differently (Figure 1, E and F). Microarray and quantitative real-time PCR analysis revealed that the expression of AP1 was significantly reduced, while the expression of its interacting genes TERMINAL FLOWER 1 (TFL1), OVEREXPRESSION OF CONSTANS(SOC1), AGAMOUS-like 24 (AGL24), SEPELLATA (SEP) and upstream genes FLOWERING LOCUS M (FLM) were increased in flower buds (Figure 2).

AP1 sequence analysis showed that the promoter, coding sequences and intron splice sites of AP1 genomic sequence in this inbred line were unchanged comparing to that in wildtype, suggesting the complexity in the regulation of AP1 in the line. Therefore these synthetic contributions caused the development of this unique phenotype. For instance, TFL1 was found to be highly expressed, and this gene can negatively regulate AP1 and specify inflorescence meristem identity leading to a delay of floral meristem formation[3]. On the other hand, the low levels of AP1 in flower buds cannot repress expression of AGL24 and SOC1, which promote inflorescence fates rather than flower formation in the meristem and result in more abundant and longer inflorescences[4]. This expression variation of these genes is subjected to a threshold[4], leading to an ON/OFF expression pattern of the master regulatory gene(s) (like AP1) to specify a floral or a stem/inflorescence meristem.

Conclusions: The inbred line identified in this study is phenotypically similar to ap1 mutants with noticeable deviations. The abnormal stem/inflorescence of the inbred line was mainly caused by significant

Figure 1(abstract P68) Phenotype of Wt and An inbred line. A: Wt; B, D-F: An inbred line.
Material and methods: In this work, phellem tissues from small branches with increasing age (1 to 7 years old) were harvested from cork oak and holm oak (a related but cork non-producing species) at the Instituto Superior de Agronomia (Portugal). Tissues collected during different growth periods were also used for analysis: samples collected during a period of high phellogen activity (April – June, 2009 and 2010) and samples collected during the inactive growth period (January, 2010). Total RNA was successfully extracted from these tissues using a protocol described by Reid et al. [4], with minor modifications.

cDNA was synthesized using standard procedures and 5′- and 3′-RACE are being performed in order to determine the full-length of putative GPAT coding sequences from Q. suber transcriptome. The expression level of Qs_GPAT5 and Qs_GPAT5 genes was assessed by quantitative RT-PCR in two different seasonal stages (April and June) in periderm cells from 3 year old branches of Q. suber. The Cp values were converted into relative quantities, using the formula, E-ΔΔCt, where E (the efficiency of the gene amplification for each primer pair) was calculated using the Real-time PCR Miner algorithm.

Results and conclusions: A cDNA fragment with 1263bp of the putative Qs_GPAT5 was obtained. The predicted amino acid sequence displays the glycerol-3-phosphate acyltransferase (PLN2499) conserved domain. Based on a database search we have identified putative orthologs of Qs_GPAT5 in P. trichocarpa (Pt_GPAT5, accession number AF0231208; Pt_GPAT4, accession number 2315213) and R. communis (Rc_ERGPAT, accession number 2531580) genome, which show high similarity to the putative Q. suber GPAT5 gene. The Rc_ERGPAT is most similar to the Qs_GPAT5 with an identity of 83% at the amino acid level. The expression profiles of GPAT4 and GPAT5 were successfully analysed during phellem differentiation in periderm collected from cork oak tree. The relative expression level of GPAT4 gene was similar in April and June. However, the relative expression level of GPAT5 gene was higher in June, which corresponds to a period of higher phellogen activity, when compared to April.

Further information on the expression of these genes in several tissues of cork oak under different developmental stages and stress conditions will also be gathered as a result of the recent effort of the Portuguese research community involved in the transcriptome sequencing of cork oak. With this work we expect to contribute to elucidate basic aspects of the molecular networks involved in cork formation.

BMC Proceedings 2011, 5(Suppl 7):P70

Background: Cork oak (Quercus suber) is a long-living species of the Fagaceae family that highly contributes for the economy of several countries such as Portugal. It is the only plant species with a phellogen capable of a sustainable production of cork with properties suited for industry applications. Phellogen, or cork cambium, usually initiates in the...
subepidermises and differentiates during the first year of growth [1]. Its meristematic activity gives rise to phellem (cork) cells to the outside and to phelloderm to the inside.

It is likely that genes involved in the regulation of other plant meristems such as shoot apical meristem and vascular cambium are also involved in the regulation of phellogen. Based on its role in other meristems, and on specific expression patterns in poplar stems, we hypothesize that SHORT-ROOT (SHR), a transcription factor from the GRAS family, may be involved in the regulation of phellogen. This gene has been well described in the Arabidopsis root where it plays a key role in the radial patterning and in regulating the specification of the root stem cell niche [2-4]. Recently, its involvement in the root vascular system to control patterning processes in the cork oak transcriptome and, at the moment, one of those sequences, putatively coding for a protein of 30 kDa (immunogen) and sequenced to determine the percent identity to known SHR gene sequences.

To analyze SHR expression patterns poplar is being used as a model tree species. Transgenic poplar plants carrying the SHR promoter fused to the GUS reporter gene have been previously generated. Stem sections collected from 1-2 year-old transgenic plants have been subject to the histochemical GUS assay and embedded in Technovit 7100 resin for detailed analysis of gene expression localization under the microscope. Characterization of SHR transcript abundance in cork oak developing stems taking into account different developmental stages and collection seasons has also been performed. Transcript abundance was analysed in stem tissues from the first to the third year of growth collected between January and October from a cork oak tree in order to cover periods of active growth and dormancy. Reproduction cork was collected in July which is the period during which the debarking process is performed from cork producer trees. RNA was extracted according to a protocol described by Reid et al. (2006) and cDNA was successfully synthesized using the Transcriptor High Fidelity cDNA Synthesis Kit (Roche). Quantitative RT-PCR was performed using LightCycler LC480 (Roche).

Results: While Arabidopsis has one SHR gene sequence in its genome, at least two additional SHR-like sequences are present in the poplar genome. Also, more than one SHR-like sequence seems to be present in the cork oak transcriptome and, at the moment, one of those sequences, Q5SHR1, consisting of 1455bp and showing strong homology to the SHR gene sequence present in public databases has been found. Further experiments are needed to elucidate the putative involvement of SHR in the regulation of phellogen. Additionally, these studies may provide tools to be used in the identification of specific expression patterns in the stem with the aim of investigating its putative function in the phellogen.

Materials and methods: Through a search in public databases we have retrieved putative orthologs of Arabidopsis SHR gene from species with a sequenced genome including Populus trichocarpa, Vitis vinifera and Medicago truncatula. Based on multiple alignments at the cDNA and deduced aminoacid sequence levels, we have designed degenerate primers in order to characterize SHR from cork oak transcriptome. The amplified PCR fragment was inserted into pCR2.1 (Invitrogen) and sequenced to determine the percent identity to known SHR gene sequences.

Conclusions: The presence of more than one SHR-like sequence in cork oak is in agreement with the hypothesis that more than one SHR gene is expressed in poplar. This is consistent with previous studies indicating that multiple SHR orthologs may exist in species with highly complex vascular systems. Further experiments are necessary to elucidate the specific function of these genes in the context of phellogen development.

BMC Proceedings 2011, 5(Suppl 7):P72

Background: Plant polyamines are preferentially detected in actively growing tissues and have been implicated in growth and developmental processes such as embryogenesis, floral developmental, fruit ripening, senescence and stress responses [1]. Recently it has been established a link between polyamines and vascular development as it was found that, in Arabidopsis, the loss-of-function mutants of ACAULISS (ACLS) gene, encoding thermospermine synthase, exhibit a severe dwarf phenotype, suggesting that thermospermine acts as a regulator of stem elongation [2,3]. However, in trees, no studies have yet been reported. Due to the relevance of vascular development in wood formation we are investigating the role of thermospermine in vascular tissues of poplar.

Materials and methods: A search for ACLS-like sequences in Populus trichocarpa genome allowed us to identify three putative ACLS orthologous genes. Based on the degree of sequence similarity, we have selected one of them, PtACLS, to generate transgenic plants bearing the constructs for overexpression and silencing of this gene in poplar.

Results: High expression levels of PtACLS in overexpression transgenic lines have been found to be correlated to higher thermospermine content in leaves and young stems, but not to a higher level of other polyamines, suggesting that PtACLS encodes a thermospermine synthase in poplar, and it is most probably an ortholog of ACLS in poplar. Interestingly, these plants display altered and arrested shoot development in the early stages following p35S::PtACLS transformation, as well as severe dwarfism. Anatomical changes associated to the lack of elongation include arrested development of the root system and no elongation of the stem from the first internode onwards. Because Arabidopsis ptACLS loss-of-function mutants show accelerated vessel cell death and ACLS expression is confined to xylem vessel elements [4], we further looked for alterations in the vascular pattern of the poplar stem, and observed the development of a wider xylem in dwarf plants, composed of primary vascular tissues only, lower number of metaxylem cells and with no secondary growth.

Conclusions: Overall, our results suggest that thermospermine has a regulatory role in xylem differentiation/maturation in poplar. Although a feedback control of thermospermine synthase seems to be present in Arabidopsis, in our transgenic poplar the high levels resulting from overexpression of thermospermine synthase gene seem to overcome any

turn-over that might be occurring of the excess thermospermine being produced. Currently we are pursuing the spatial localization of the ACLS transcript in poplar plants through in situ hybridization, and by taking advantage of the generated transgenic lines we hope to understand the role of thermospermine in the vascular tissues formation in this woody species.

A direct stimulatory role of mobile gibberellin in Arabidopsis hypocotyl xylem expansion

1Department of Plant Molecular Biology, University of Lausanne, Switzerland
E-mail: kaisa.nieminen@unil.ch

BMC Proceedings 2011, 5(Suppl 7):P73

Background: Can Arabidopsis research contribute to our understanding about wood development? Does the function of vascular cambium in a herbaceous weed resemble that of a tree? Despite its diminutive size as compared to a tree, Arabidopsis still displays cambial driven secondary thickening in several organs, including the hypocotyl. Hypocotyl is a good model organ for wood development studies, as in this organ the radial secondary development can be uncoupled from the apical primary growth. This is due to the fact that the hypocotyl elongates only for five days after germination; thus, the radial secondary growth starts only after the elongation has ceased. This is in contrast to the other Arabidopsis organs displaying cambial growth, where it is accompanied by the simultaneous activity of the shoot and root meristems.

Two phases can be identified in the hypocotyl secondary development: 1) an early phase of proportional radial growth, where the cambium produces both xylem and phloem at a similar rate, and 2) a later xylem expansion phase, where more xylem than phloem is produced (Fig 1A) [1]. Notably, the composition of xylem is different between these two phases: the xylem produced during the first phase consists of xylem vessels and parenchyma cells, and of xylem vessels and fibers during the second phase. Especially the later phase, characterized by extensive wood formation, resembles the secondary growth in tree species.

We have previously shown that in Arabidopsis hypocotyl the transition from the first to the second phase is triggered through the onset of flowering, when the identity of shoot apical meristem changes from vegetative to reproductive [1]. Upon this transition, instead of new leaves, an inflorescence stem emerges from the middle of rosette leaves. What could be the nature of this signal [2]?

Results and discussion: Does flower differentiation trigger the onset of xylem expansion? To study this, we analyzed Arabidopsis null mutants for key flowering regulators. We were able to confirm that xylem expansion took place in all our mutants, suggesting that neither floral specification nor bolting (the emergence and elongation of the inflorescence stem from the rosette) are required for this process.

Thus, our signal appeared to be upstream of flowering: possibly the same signal activated both flowering and xylem expansion? Since gibberellin hormone (GA) has been shown to be an important regulator of flowering initiation, we wondered what effect it would have on the secondary growth. Indeed, both xylem expansion and flowering were initiated upon
GA treatment. To study if GA biosynthesis was required for xylem expansion, we analyzed ga1-3, a null mutant for the GA REQUIRING 1 gene encoding a key GA biosynthesis enzyme. As expected, these plants displayed strongly reduced xylem expansion. Next we wanted to study, if not only the GA content, but the actual level of GA signaling, was important for the regulation of xylem expansion. We observed that the transgenic and mutant lines with elevated GA signaling displayed increased and the lines with impaired GA signaling accordingly reduced xylem expansion, thus confirming the rate-limiting role of GA in this process.

Does GA signaling stimulate xylem expansion at the cambium, or does it function at the shoot apex to launch the production of the mobile signal? To study this, we performed grafting experiments (Fig 1B). We could see that the wild-type level of GA signaling in either part of the graft could not rescue the xylem expansion if the other part was dominantly inhibited in GA signaling. Accordingly, elevated GA signaling level enhanced xylem expansion only locally; the effect was not graft-transmissible to the wild-type part of the graft. Thus, GA signaling cascade appears to act as a local regulator of cambial activity, downstream of the mobile signal. Could the GA hormone itself be mobile? We studied this by reciprocally grafting the GA deficient ga1-3 mutant with a wild-type plant. Strikingly, in these plants, the wild-type scion (shoot part) restored xylem expansion in the hypocotyl of the ga1-3 stock (root part) (Fig 1C). To sum up, an impaired GA signaling did not affect xylem expansion systemically, confirming that it acts downstream of the mobile cue. By contrast, the GA effect was graft transmissible, confirming that GA itself is the mobile shoot-derived signal.

Conclusions: Our study shows that GA acts as a mobile signal that activates the onset of extensive xylem production in Arabidopsis hypocotyl. It would be interesting to study if a similar GA driven process takes place also in tree species upon the seasonal or age-related activation of their cambial growth. We think that Arabidopsis research has the potential to contribute novel hypotheses into secondary development research, and that it can complement tree studies in some areas of this research field. However, due to the sheer extend of secondary development present in tree species, and their other special characteristics (the seasonal activity-dormancy cycle etc.), many processes of secondary growth remain to be best studied in trees.

Deep sequencing combined with microarray hybridization to identify novel and conserved microRNAs during somatic embryogenesis of hybrid yellow-poplar (Liriodendron chinense (Hems.l.) Sarg. × L. tulipifera Linn.)
Li Tingting, Chen Jinhui*, Shi Jisen*, Xu Jin*
The key laboratory of forest genetics and gene engineering of the ministry of education of China Nanjing Forestry University Nanjing 210019, China E-mail: xjinshh@njfu.edu.cn
BMC Proceedings 2011, 5(Suppl 7):P74

Background: Hybrid yellow-poplar was a man-made cross between Liriodendron tulipifera Linn. × L. chinense(Hemsl.) Sarg. Heterosis was strong both on growth and adaptation, no matter what, the crosses or the reciprocals. During the last 12 years, somatic embryogenesis systems were successfully established in our lab, in order to meet the needs of planting materials for expanding plantations in Southern China. Synchronous development of high quality embryos was always required both for the study of embryo development, and the supply of commercial emblings. The functions of plant microRNAs (miRNAs) in post-transcriptional gene regulation by targeting mRNAs for degradation, or the translational repression by hybridizing to complementary sequences within target mRNA molecules were well reported [1]. One of the major roles of miRNAs in regulating plant development has been obtained from a number of studies but molecular mechanisms regulating the development of embryos are not well understood, especially during the early stages of somatic embryos [2]. Here we present some results on the discovery of novel and conserved miRNAs during somatic embryogenesis of hybrid yellow-poplar using Illumina sequencing and miRNA microfluidic chip in order to...
understand how the embryonic somatic mass is developed into embryos and plants.

**Materials and methods:** The pre-embryo mass (PEM) and different stages of somatic embryos (SE) (Figure 1) were collected sequentially from the hybrid yellow-poplar somatic embryogenesis system. All the callus and embryo tissues were staged by microscope and immediately frozen in liquid nitrogen and stored at -80°C until used. Total RNA was isolated from different developmental stages of somatic embryogenesis using Total RNA Purification Kit (Norgen Biotech Corporation, Canada). All the RNA samples from different somatic embryo tissues were mixed equally to form a single RNA pool. Following the instruction of LC Science, small RNA sample was prepared and then sequenced using Illumina Technology. Processing and analysis of raw data was done following Sunkar et al [3,4]. Conserved and candidate novel miRNAs in hybrid yellow-poplar were identified. A mixed small RNA microarray hybrid was used to validate the sequencing result and detect new miRNAs in hybrid yellow-poplar; 299 sequences detected by sequencing and 1,450 plant miRNAs sequences in miRBase 15.0 were ordered to serve as probes. A well-developed stem-loop strategy [5]and SYBR Green master mix were used to perform real time PCR to validate the miRNAs expressed in both sequencing and microarray analysis. The potential targets of miRNAs were predicted using the psRNATarget program (http://bioinfo3.noble.org/psRNATarget) with default parameters. The biology and molecular functions of these predicted targets were categorized by the Gene Ontology program (http://www.Geneontology.org/).

**Results:** A total of 17,214,153 reads representing 7,421,623 distinct sequences were obtained from a short RNA library generated from small RNA extracted from all stages of somatic embryogenesis tissues. Hybrid yellow-poplar has a complex small RNA population and the length of small RNAs varied. The 24-nt and 21-nt are the predominant length for the majority of the small RNAs. Combining deep sequencing and bioinformatics analysis there were 82 sequences, with perfectly matched known miRNAs from 32 conserved miRNAs families and 273 species-specific candidate miRNAs whose precursors were generated from Liriodendron tulipifera ESTs and form good hairpin structure. Among these miRNAs, both miR156 and miR166 which have been reported to be important during plant early embryonic patterning, had a large family members expressed in this process. Microarray hybridization and qRT-PCR technology were used to demonstrate that most conserved and species-specific miRNAs expressed in hybrid yellow-poplar. In addition, another set of 149 miRNAs included in 29 conserved families was found, which were not discovered by deep sequencing analysis but have obvious detectable signals in the microarray. Potential targets of biological processes and molecular functions of these miRNAs were predicted by blasting with Arabidopsis thaliana and analyzing with Gene Ontology. These predicted target genes participate in many metabolic and biological processes and molecular functions.

**Conclusions:** By combining Illumina deep sequencing with microarray hybridization we discovered 231 miRNAs from 61 conserved miRNA families and 273 species-specific candidate miRNAs. The potential miRNA targets were varied in various biological and metabolic processes. These results indicate that microRNAs play wide-ranging and important roles during all stages of somatic embryogenesis in hybrid yellow-poplar. Additional experiments on the functional verification of interesting candidate miRNAs are now under consideration.

**PT5 Phytohormone targeting in plant tissues**

*Miroslav Strnad*, Ondrej Novak, Jakub Rolcik, Danuse Tarkowska, Jiri Gruz, Karel Dolezal

**Background:** The identification and quantification of plant hormones in plant tissues are necessary for physiological studies of their metabolism and mode of action. The major problem associated with plant hormone analysis is that the amount of phytohormones present endogenously in plant tissues is very low, usually in the range of fmol to pmol/g fresh weight.

**Methods:** Homogenization and extraction with organic solvents was done in one microcentrifuge tube and accelerated by crushing the plant material in a vibration mill. The extracts from minute amounts of fresh plant material were immediately purified using a solid-phase extraction (C18, C8, Oasis™ HLB cartridges) in combination with ion-exchange and/or immunoaffinity purification. A fast chromatography technique, the ultra performance liquid chromatography (Acquity™ UPLC,Waters) was coupled to triple quadrupole mass spectrometer (Xevo™ TQ MS, Waters) equipped with an electrospray interface (ESI) and the unique performance of collision cell – ScanWave™. The mass spectrometric conditions were optimized for each analyte and quantification was obtained by multiple reaction monitoring (MRM) of precursors and the appropriate product ions.

**Results and discussion:** We found that a combination of different sorbents, reverse phases and ion-exchange phases, was the best tool in the one-step purification, giving a total extraction recovery ranging between 50-80% for all studied biologically active compounds. In RM mode, the detection limit for most of phytohormones (cytokinins [1,2], auxins [3], abscisic acid [4], gibberellins, brassinosteroids) as well as phenolic acids [5] and mammalian steroids [6] was close to 1 fmol and achieved linear range was at least five orders of magnitude. Use of our procedures can allow the quantification of plant hormones and their derivatives (in total 145 compounds) in very limited amounts of material, ca. 100 mg FW. The methods provide substantial improvements in terms of robustness, sensitivity, selectivity, convenience, through-put and cost-effectiveness over previous methods published.

**Conclusions:** The application of new analytical approaches based on UPLC separation makes possible a new direction in plant hormone research. We believe that UPLC-ESI(+)/MS/MS technology can be used for fast and sensitive quantitative analysis showing reproducibility in the plant hormones profiling in different tree extracts.

BMC Proceedings 2011, 5(Suppl 7):P76
Cortical microtubules are cytoskeletal components that are relevant to the bioenergy and forest products industry due to their postulated role in orchestrating cellulose microfibril deposition during cell wall formation. The microtubule component proteins α-TUA and β-tubulins (TUB) are encoded by multi-gene families with very high overall sequence homology across species. To advance our initial characterization studies (Oakley et al., 2007), we have developed a suite of transgenic Populus that exhibit perturbed TUA to TUB transcript ratios, that express tubulin PTM mimics. Most of the construct combinations resulted in abnormal organogenesis and vascular development, and failed to produce viable plants. Only three of the combinations led to whole-plant regeneration, and interestingly, all three featured the C-terminal variants. This is significant because the C-terminus is the post-translational modification (PTM) hot-spot in animal tubulins. One of the PTM mimics that we developed lacks a C-terminal tyrosine, thought to be the target of a tyrosine cleavage and re-ligation cycle important for tubulin regulation in animal cells. The transgenic trees appeared morphologically normal, but exhibited a range of epinasty and twisting phenotypes in mature leaves. Bark color was noticeably lighter in the transgenics. Microfibrill angle, wood density, lignin content, lignin structure and metabolic profiles were altered in the transgenic wood. The results are consistent with a function of microtubules and microtubule PTMs for plant development and cell wall biogenesis in Populus, and offer novel strategies to manipulation of wood properties.

BMC Proceedings 2011, 5(Suppl 7):P77
The raffinose family of oligosaccharides (RFOs) likely fulfill at least few major physiological roles in plants, translocation of carbon in the phloem, storage in sink tissues, and as putative biological agents to combat both abiotic and biotic stress [1-3]. The synthesis of galactinol from myo-inositol + UDP-galactose, by galactinol synthase (GolS), is considered a key regulatory step in RFO synthesis [4]. To investigate the functional roles of this class of compounds in trees, two cDNAs that encode galactinol synthase (GolS), were identified and cloned from hybrid poplar (P. alba × grandidentata). Phylogenetic analyses of the Populus GolS isoforms with other known galactinol synthases suggested a putative role for these enzymes during biotic or abiotic stress in hybrid poplar. The predicted protein sequences of both isoforms (PaxgGolSI and PaxgGolSII) showed characteristics of galactinol synthases from other species, including a serine phosphorylation site at position 266 and the pentapeptide hydrophobic domain AAAP [5]. Kinetic analyses of recombinant PaxgGolSI and PaxgGolSII resulted in Km values for UDP-galactose of 0.79 and 0.65 mM and Vmax values of 660.4 and 1245 nM min-1, respectively. PaxgGolSI inherently possessed broader pH range and temperature sensitivity when compared to PaxgGolSII. Interestingly, spatial and temporal expression analyses revealed that PaxgGolSI transcript levels varied seasonally, while PaxgGolSII did not, thereby implying a temperature-regulated transcriptional control of this gene in addition to the observed thermosensitivity of the respective enzyme. Based on this evidence, we suggest that PaxgGolSI may be involved in basic metabolic activities (i.e. storage), while PaxgGolSII is likely involved in seasonal mobilization of carbohydrates.

References
Results: Testing for significant differential expression identified 106, 208 and 464 mRNAs that showed different abundance 24 hours after withdrawal of PGRs, during differentiation of early embryos and development of late embryos, respectively. 53 mRNAs were present in more than one set, giving a total of 720 unique transcripts. The reliability of the microarray results was confirmed by qRT-PCR.

The relative abundances of Gene Ontology (GO) terms within the sets of differentially expressed genes were compared against the GO distribution of all clones on the array. We observed a general over-representation of genes involved in response to stress, both during the transition from proliferation to differentiation of early embryos and from differentiation of early embryos to development of late embryos. During transition from early to late embryogeny, genes involved in catabolic processes, in carbohydrate metabolic processes and in gibberellin (GA)-mediated signaling were over-represented, while genes involved in metabolic processes were under-represented.

Our data show that already 24 hours after withdrawal of PGRs, the elimination of cells by PCD has been initiated as PCD-related genes like METACASPASE 9 (MC9, AT5G04200) were up-regulated. During differentiation of early somatic embryos, the first week after withdrawal of PGRs, genes related to cell wall modifications were down regulated. An increase in transcript accumulation was observed for genes coding for developmental regulators like MATERNAL EFFECT EMBRYO 1 (ME1, AT2G28580), and a decrease of transcripts coding for LOB-DOMAINS containing proteins, indicating that pattern formation has started. The analysis revealed a putative increase in the content of both auxin and gibberellin.

At the developmental switch to late embryogenesis, several genes of importance for cell organization, developmental processes, and other biological processes were up- or down-regulated. The relative transcript abundance of LIL, ROXY 1 (AT3G02000) and WRKY6 (AT1G62300) decreased while the abundance of transcripts such as AB13, AB14 (AT2G02200) and GROWTH-REGULATING FACTOR 1 (GRI1, AT2G22840) increased. In addition, genes coding for the LEA proteins were up-regulated. These changes in transcript levels suggest that pattern formation continued and that maturation had initiated at this developmental stage. The transcript levels of genes encoding a fatty acid elongase, FIDDLHEAD (FDH, AT2G26250), which regulates epidermal cell differentiation, and for an EXTRACELLULAR DERMAL GLYCOPROTEIN (EDGP, AT1G03230) were decreased. Transcripts encoding SURI1, MYB77 (AT3G50060), the auxin-induced protein INDOLE-3ACETIC ACID INDUCIBLE 11 (IAA11, AT4G28640), the auxin receptor TRANSPORT INHIBITOR RESPONSIVE 1 (TIR1, AT3G62980) and a positive regulator of brassinosteroid signalling (AT1G78700) were up-regulated, indicating that the auxin-responsive machinery was up-regulated. Furthermore, genes encoding the GA signaling repressors were up-regulated, while a GA induced and a gene encoding for a GA inactivating enzyme were down-regulated.

Discussion: By examining changes in global gene expression, we have been able to determine the timing of molecular events regulating putative processes during embryogenesis based on the assumption that the conifer genes are homologous to their Arabidopsis counterparts. We recognize notable changes in the expression of genes involved in regulating auxin biosynthesis and auxin response, gibberellin-mediated signaling, signaling between the embryo and the female gametophyte, tissue specification including the formation of boundary regions, and the switch from embryonic to vegetative development. In addition, our results confirm the involvement of previously described processes, including stress, differentiation of a proderm and programmed cell death. Our analyses of genes and putative processes that take place during differentiation of early embryos and development of late embryos in a conifer can now serve as a basis for further studies of the processes.

Background: The cultivation of poplars (Populus spp.) is favored for forestry and reclamation purposes all over the northern hemisphere where they represent a commercially important resource. Poplars may become a component of programs to optimize carbon sequestration however; poplars are generally regarded as drought sensitive. The patterns of episodic drought over the last decade suggest that the development of drought tolerant poplar genotypes could be a useful tool to achieve sustained forest productivity [1].

Previous reports have shown that expression of hundreds of poplar genes changes in response to drought, presenting a problem in the identification of genes that are functionally important than others in counteracting the harmful effects of drought [2,3].

The genus Populus contains many fast growing hybrids that show varied drought tolerance according to genotype [4]. Hence, there is genetic variation among poplar hybrids that can be used to identify genes that contribute to drought stress tolerance. Despite extensive physiological and morphological descriptions of the response of Populus to drought, little work has been undertaken to explain genotype differences at the gene level. Therefore, this research has been undertaken and its major objective is to identify the genes that contribute to drought stress tolerance in poplar by correlating the physiological responses to gene expression. These genes may potentially be used as molecular markers in drought tolerance breeding programs.

Materials and methods: Hardwood cuttings of 9 poplar hybrids (Green Giant, Assiniboine, AP-36, Canam, Katepwa, Hill, Walker, WP-69 and WP-86) were obtained from Dr. Barb Thomas (Alberta Pacific Forest Industries) and Bill Schroeder (Agriculture & Agri Food Canada, Indian Head, Saskatchewan). Cuttings were established in the greenhouse and plants were obtained for the drought stress trial. At the start of the trial, water was withheld from plants used for drought experiment whereas control plants were watered regularly. During the drought stress trial, a plasticochron index was established that helped to collect the data from similar leaves of all drought stressed and control plants. Data were collected from 9 different poplar hybrids at 3 time points (mild stress, severe stress and recovery). Split plot design was used to collect the data from drought stressed and control plants using genotypes as main plots (9) and time points as sub-plots (3). Physiological data were collected for height growth, new leaf formation, water potential (Ψ) and relative water content (RWC) from drought stressed and control plants. Young leaves were also collected for gene expression analysis from both stressed and control plants. Quantitative polymerase chain reaction (Q-PCR) was used to analyze the expression of several candidate drought responsive genes.

Results: Drought significantly affected the growth of the trees (Figure 1). Data from 3 drought stress trials in the greenhouse showed that different hybrids responded drought stress differently. Some hybrids behaved as tolerant whereas others as sensitive and some hybrids showed intermediate response to drought. By statistical analysis of physiological data, we ranked these 9 poplar hybrids according to their drought tolerance ability. Statistical analysis showed that Walker maintained significantly better height growth, leaf formation, Ψ and RWC during mild, severe stress and recovery as compared to all other hybrids; therefore Walker was identified as the most drought tolerant hybrid genotype. On contrary, Green Giant showed poor maintenance of physiological parameters at all time points and hence was regarded as the least drought tolerant hybrid genotype. An intermediate response of all other hybrids was recorded during 3 drought stress trials in the greenhouse. Further, we focused only on 2 genotypes (the most and the least drought tolerant) to analyze the expression of several candidate drought responsive genes, which were obtained from microarray studies in poplar.

Q-PCR results revealed that selected 2 genotypes had no significant effect
on the stress response of some genes, however, other genes showed marked and significant differences in expression between the two genotypes.

**Conclusions:** • Three trials in the greenhouse showed that physiological response to drought varies among different poplar hybrids.
• Walker was identified as the most whereas Green Giant as the least drought tolerant genotype among a group of poplar hybrids.
• Q-PCR analysis showed that among a set of candidate drought responsive genes, some genes showed differential expression between the most (Walker) and the least (Green Giant) drought tolerant genotypes.
• The genes showing differential expression in the most and the least drought tolerant genotypes might be playing an important role in drought tolerance of poplar.
• We have identified *Populus* genes those expression correlate with drought tolerance, providing candidate genotypes for drought tolerance breeding.
• These genes may also be used as molecular markers for drought tolerance in *Populus*.

**BMC Proceedings** 2011, 5(Suppl 7):P80

The Pinewood nematode *Bursaphelenchus xylophilus* (PWN) was found to be responsible for maritime pine (*Pinus pinaster*) death for the first time in Europe in 1999, in a Portuguese forest south of Lisbon. It is the causal agent of the Pine Wilt Disease (PWD) and a quarantine organism in the European Union with approximately 680 million spent from 1999 – 2009 for attempting its eradication, which must also be added to direct losses from tree mortality. During this period, important progress has been made in understanding the relationship between PWN, its insect vector and the host tree/environmental factors that result in pine wilt in all countries affected but, especially, in Portugal.

Although PWN can cause devastating tree mortality, there is also evidence that some tree species or individual trees within a species are either tolerant (i.e. support the nematode, but are not killed immediately) or resistant to the nematodes. In order to investigate the susceptibility of *Pinus pinaster* to *Bursaphelenchus xylophilus* as a first step for the establishment of methodologies for the improvement of its resistance, a research program was implemented recently in Portugal for this species, combining genomic and quantitative genetics approaches. Until now, more than 500 trees were phenotypically selected in a highly affected stand and monitored during two years, regarding their phytossanitary status. The percentage of mortality observed in the first year was about 10%, with this value decreasing to less than 5% in the second year.

Around 200 trees (including 150 of the selected trees) were genotyped for 6 microsatellite loci and three combinations of AFLP markers. The genotyping results show a high diversity of genotypes, which may open good prospects for the selection of resistant plants to *Bursaphelenchus xylophilus*.

At the same time, genomic and transcriptomic studies have been initiated with the final goal to discover candidate genes, loci and molecular markers related with disease resistance to PWN. With regards to the effects of the disease at a transcriptional level, the SSH technique was utilised to identify ESTs in *P. pinaster* and *P. pinea* when inoculated with PWN. ESTs were isolated, cloned, sequenced and identified using BlastN and BlastX, and clearly indicated that at an initial stage of the disease there is activation of a defence response at a molecular level, mainly related to oxidative stress, production of lignin and ethylene and post-transcriptional regulation of nucleic acids. 58% of the isolated sequences are not yet described, which shows the lack of genomic information currently available for pine. The results obtained are presented and discussed.

**BMC Proceedings** 2011, 5(Suppl 7):P81

Eucalyptus globulus is an important species for pulp production in Chile; however it has a high sensitivity to frost. During the last few years, many studies have directed their efforts to elucidate the molecular mechanisms that regulate plant response to cold stress through the analysis of gene expression. This work reports the isolation and characterization of coding and non-coding sequence of three dehydrin genes of *E. globulus* which allowed comparing the gene expression of these genes during cold acclimation, the type of dehydrin and the presence of regulatory elements in their promoters which provided valuable information about the possible signaling pathways and regulation of these genes. The three dehydrins identified in *E. globulus* showed a high transcript accumulation in stem and leaf tissue of acclimated plants, compared to non-acclimated, and the highest transcript accumulation was observed after the exposition of plants to night frosts (-2°C). Furthermore, the freezing resistant genotype exhibited a higher transcript accumulation after frost exposition compared to the sensitive genotype. These results support the idea that dehydrin proteins have an important role during cold acclimation and frost tolerance in *E. globulus*.

**BMC Proceedings** 2011, 5(Suppl 7):P82

**Background:** Plants are able to incite a type of broad spectrum resistance against pathogens upon pre-treatment with biological or chemical inducers. Systemic Acquired Resistance (SAR) and Induced Systemic Resistance (ISR) are two types of induced resistance which lead to the accumulation of specific pathogenesis-related (PR) proteins. Non-pathogenic rhizobacteria are inducing agents for ISR and increased levels of ethylene (ET) and jasmonate (JA) are associated with this pathway, whereas SAR is associated with an increase in salicylic acid (SA) levels [1]. *Pinus patula* and *P. radiata* are commercially planted conifer species in South Africa, but are both highly susceptible to the causal agent of pitch canker, *Fusarium circinatum*. Annually, the forestry sector suffers substantial economic losses due to this disease which affects 20-30% of
the planting stock. Bonello et al. (2001) showed that repeated mechanical inoculation of P. radiata with F. circinatum activated induced resistance, enhancing the protection of the tree against subsequent pathogen challenge [2]. Detailed knowledge of the molecular mechanisms underlying induced resistance may be useful to develop strategies to control diseases of pine trees. This study aimed to compare the efficiency of ten biological and chemical inducers in inciting resistance against F. circinatum. Additionally, the molecular basis of this induced resistance was investigated by analyzing the response of selected putative defence response genes.

Methods: Ten activators of induced resistance (Bion®, Messenger®, Chitin, MeJA, Fusarium oxysporum, Pseudomonas fluorescens, SA, Kannar, Ralstonia solanacearum and potassium phosphate monobasic) were compared. A set of 80 P. patula seedlings were used per treatment. Inducers were applied at four and six months of age and F. circinatum spores (1x10⁴) were used to challenge the seedlings a week after the booster application (six months). Disease severity was assessed six weeks after inoculation by comparing the size of the lesions on treated plants to water control plants. Three inoculations that caused symptoms most successfully were selected for further analysis. A set of 116 plants per treatment were screened weekly for eight weeks. Aerial parts of the six month old plants were harvested for RNA isolation at 24 hrs after the second application. For each treatment, three replicates, with 12 plants per replicate, were harvested. Subsequently, RNA was extracted for the reverse transcriptase quantitative PCR (RT-qPCR) analysis, where four putative defence genes were profiled using the Roche LightCycler® 480 instrument.

Results and discussion: MeJA, Messenger and chitin treatment resulted in the reduction in symptom severity (results not shown). MeJA, Messenger and the deacetylated version of chitin, chitosan were then tested under stringent inoculation conditions with F. circinatum to verify the effectiveness of the inducers. The most promising treatment was chitosan at a concentration of 10 mg/ml, which resulted in a significant reduction in lesion length over a period of 6 weeks. Lesion lengths were converted to percentage live stem (calculated as lesion length divided by plant height multiplied by 100) and are displayed in Table 1.

The defence response elicited by chitosan application was investigated. Four putative genes, representing the onset of SAR and ISR were analyzed (Table 2). Phenylalanine ammonia lyase (PAL) had a three-fold accumulation in transcript expression in comparison to uninoculated plants (Table 2). The expression level of the 1-deoxy-D-xylulose-5-phosphate synthase (DXS) gene, which catalyses the methyl erythritol-4-deoxy-D-xylulose 5-phosphate synthase and 1-hydroxy-2-methyl-2-(E)-butenyl 4-diphosphate reductase genes. *p<0.05, Kruskal-Wallis test.

known to lead to the production of secondary metabolites to elicit resistance.

Conclusion: The potential of priming P. patula to defend itself against pathogen attack was explored. We tested the application of ten different inducers to enhance tolerance to F. circinatum. The application of chitosan reduced pitch canker symptoms. Reduced lesion length was observed for a period of six weeks, indicating the activation of induced resistance. Further molecular analysis suggests that the treatment may activate the phenylpropanoid pathway, which is involved in the production of secondary metabolites that have antifungal properties [4].

Entire defence response pathways influenced by chitosan application in P. patula will be investigated in subsequent expression profiling assays.

Trees are exposed to a variety of pathogenic fungi. The defense response toward a biotroph may require a different strategy that toward a necrotroph. To understand the key processes of defense responses toward pathogenic fungi in aspen (Populus tremulae) at the transcript level we inoculated clones of this species with a foliar rust and a necrotroph in the bark. Leaf samples were collected from above the inoculation site to examine the long distance (systemic) defense responses and bark tissue around the site of inoculation examined for the local response as early as day1 post treatments. We performed microarray experiments on the biotrophic and necrotrophic interaction and between healthy controls of two SwAsp clones. Selected candidate genes were also examined in more detail by qRT-PCR and chemical analysis for phenols and tannins was also performed. We found that the two clones

Heterobasidion annosum senso lato is the most devastating pathogen of conifers such as Norway spruce in Europe. This pathogen enter Norway spruce trees trough the roots or wounds and colonizes the tree from within, growing as a saprophyte when established within the dead heartwood and acting as a necrotroph when in contact with living host tissue. We have examined the host response in Norway spruce at the molecular level as well as the responses of the pathogen.

We have studied the defense reactions toward pathogenic fungi in the ecological and economic important conifer Norway spruce from both a molecular and anatomical perspective. We have studied the host responses of the tree as well as the attack modes and genes induced by its pathogens. The disease caused by this H. annosum s.l. is complex as it is can act both a necrotroph and saprotroph as well as a broad host range. Twenty percent of the trees in Norwegian spruce stands tend to be infected by this pathogen and H. annosum s.l. typically colonize and decay the economically important wood inside the trunk. However, Norway spruce have defences against this and other pathogens and the attack can be fought off by the living bark and sapwood but not the heartwood being composed of dead zylen.

The bark has effective defense reactions that can be induced and we have seen indications of systemic and primed defense responses but also the sapwood has defensive capabilities. The tree has a unique defense against this internal attack by forming a reaction zone; in this case the host defense is directed inwardly by the still living sapwood toward the central colonized wood. We have studied the host defense at the transcriptional level, changes in phenols and lignification and found that the speed of the host response appear to be crucial in fending off the pathogen.

BMC Proceedings 2011, 5(Suppl 7):P85

Background: Nitrogen is a major limiting factor of plant growth in many ecosystems. Root nodule symbiosis (RNS) is one of the most efficient adaptations allowing plants to cope with nitrogen deficiency by establishing a symbiotic association with diazotrophic bacteria able to produce ammonium from atmospheric nitrogen. Nevertheless RNS is restricted to two groups of plants: legumes and Parasponia (Celtidaceae), that interact with a group of gram-negative proteobacteria collectively called rhizobia, and actinorhizal plants, a group of 220 species, mostly shrubs and trees distributed in the orders Fagales, Cucurbitales and Rosales, that interact with gram-positive actinomycetes of the genus Frankia[1]. All these plants belong to the Rosid I clade, suggesting a common origin for the ability to establish RNS [2].

In recent decades a strong research effort focused on model legumes lead to the identification of key molecular actors involved in nodulation, including the bacterial signalling molecules, the Nod factors and several genes involved in the symbiotic signalling pathways [3]. Much less is known in non model legumes and actinorhizal plants, particularly in species that are not infected like model legumes through root hair but show more ancestral infection mechanisms like crack entry or intercellular infection. Yet important cues regarding the diversity and evolution of RNS are being found precisely in these more primitive non-model systems [4,5].

Acting infection mechanisms leading to root nodule symbiosis, the intercellular infection pathway is probably the most ancestral but also one of the least characterized [6,7]. Intercellular infection has been described in Discaria trinervis, an actinorhizal shrub belonging to the Rosales order [8]. To decipher the molecular mechanisms underlying intercellular infection with Frankia, we set up an efficient genetic transformation protocol for D. trinervis based on A. rhizogenes.

Methods: We analyzed the susceptibility of D. trinervis to two strains of A. rhizogenes: A4RS, and ARqua1; both strains contained a pHKN29 plasmid with a 35S::GFP fusion [9]. The classic in-vitro inoculation was compared to an ex-vitro method reported to be successful in several plant species [10]. The functionality of the symbiosis was tested on co-transformed plants by performing nodulation tests and acetylene reduction assays. Using this technique, we introduced the promoter of MtEnod11, a nodulin gene from M. truncatula widely used as a marker for early infection-related symbiotic events in model legumes [11].

Results: Transgenic roots showing strong levels of GFP were obtained for all treatments. The ex-vitro method using Arqua1 was the best compromise to obtain a good co-transformation efficiency while minimizing the impact on root system architecture. Co-transformed roots were specifically and efficiently nodulated with Frankia and the resulting nodules were undistinguishable from non-transgenic nodules in terms of developmental timing, anatomy, nitrogen fixation and feedback control by nitrogen. The expression of reporter genes such as GUS and GFP could be easily detected within transgenic D. trinervis root systems. The promoter of MtEnod11 retained its symbiotic activation in transgenic D. trinervis nodules. Similar results were obtained in C. glauca[12].

Conclusions: These findings open new avenues to study the genetic mechanisms of intercellular root invasion and single cell infection, allowing detailed characterization of genes involved in D. trinervis nodulation and a better understanding of the most ancestral infection pathways leading to RNS. In addition, because D. trinervis belongs to the Rosales order, evolutionary comparisons can be made with plants belonging to the same clade but unable to nodulate (most Rosaceae), or with Parasponia sp., the only non-legume able to enter RNS with rhizobia. The transformed roots in D. trinervis with appropriate reporter genes would be a powerful tool to explore signaling mechanisms in symbioses with this ancestral infection mode [13].

References
Progressive increase of temperatures as well as longer seasonal drought periods revealed by climate studies correspond to fast environmental changes that forest species face with their actual genetic background. Natural selective processes cannot develop an adaptive response within this time frame. Thus the capability of forest tree species to adapt to the new environments will depend on their genetic background, but also rely on their phenotypic plasticity. Several reports have shown the involvement of epigenetic modifiers as the basis of the phenotypic plasticity, and in particular to the adaptation to abiotic stresses. DNA methylation (methylation of cytosine residues) is one the most important epigenetic mechanisms which control adaptation in this ancient taxonomic group. To better understand these processes, we designed a strategy which integrates several approaches:

1. Phenotypic characterization in response to drought, evaluating functional responses of forest trees to drought for long time. The latest experiment was designed to better understand the functional mechanisms of drought tolerance. In 2011 a third experiment will be developed to evaluate survival capacity.

Recent climate evolution studies highlight the progressive temperature increase and prevalence of seasonal drought, with specially incidence in the Mediterranean region. Although confers are very important species regarding forest conservation, sustainability and productivity, given the large forest surface they cover in Spain and their active role in preventing soil erosion and desertification, we know little about the molecular mechanisms which control adaptation in this ancient taxonomic group. The work is focused on the study of adaptive responses of maritime pine (Pinus pinaster Ait.), one of the most important gymnosperm species in the Mediterranean region. To better understand these processes, we designed a strategy which integrates several approaches:

1. Transcriptome analysis. ESTs collections associated with different tissues and growth conditions. We developed: a) Subtractive cDNA libraries. In order to improve the phenotypic estimates, clonal material was generated by vegetative propagation and several ramets per clone were analyzed per experiment. Two experiments have been already developed: a) Plants from a complete full-sib family were exposed to severe drought for a short time; b) Selected clones showing contrasting behavior in their response to drought were subjected to a moderate drought for long time. The latest experiment was designed to better understand the functional mechanisms of drought tolerance. In 2011 a third experiment will be developed to evaluate survival capacity.

Background: The hemoglobin produced by Vitreoscilla bacterium, VHb, is capable to promote the respiratory activity and ATP production under hypoxic conditions [1]. In micro-organisms grown under oxygen-limited conditions, the heterologous VHb expression improves the production of primary and secondary compounds, growth, as well as stress tolerance [2,3]. VHb has also been shown to protect plants against deleterious effects of nitric oxide (NO), the important signalling molecule produced during pathogen challenges [4]. We have previously studied the VHb expressing hybrid aspen lines (Populus tremula L. x tremuloides Michx.) under elevated UV-B illumination and showed that the VHb lines had increased secondary metabolite production and also enhanced accumulation of starch in the chloroplasts when grown in standard greenhouse conditions [5]. In order to reveal the effect of VHb on the expression of stress-related genes in hybrid aspen exposed to biotic stress, we conducted experiments with pathogenic fungus and larvae of insect herbivore.

Materials and methods: In the herbivory experiment, two-year-old VHb line and non-transgenic hybrid aspen line were exposed to the feeding of chestnut moths larvae (Conistra vaccinii L.) for 24 hours. Four VHb hybrid aspen lines and two non-transgenic hybrid aspen lines were infected with pathogenic fungus Venturiatremulae, in vitro. Samples for the RNA and protein extractions were collected after 10 and 21 days of the pathogen inoculation. In both experiments, the transcriptome changes were studied with microarrays and real-time RT-PCR. The CDNA slides contained 8256 stress-related oligos of Populus euphratica. The relative expression of selected genes were conducted with the LightCycler® 2.0 (Roche) and LightCycler® 480 instruments according to the manufacturer's chemistry. The amount of VHb protein during pathogen fungus experiment was analysed by Western blots.

Results and conclusions: The consumption of the leaves by the chestnut moth larvae was comparable on the non-transgenic and the VHb line. The effect of herbivory to the gene expression levels of wounded and systemic leaves was similar in the VHb and non-transgenic hybrid aspen lines, but in the non-transgenic line, the detected changes were more severe than in the VHb hybrid aspen line. The genes encoding bark storage proteins (BSPs), copper chaperone (CCH), and nitrate transporter (NRT) were among the limited number of genes which showed different expression changes between the VHb and non-transgenic hybrid aspen line.

The hybrid aspen lines infected with V. tremulae showed symptoms of shoot blight i.e. blackened stems and leaves, but the amount of VHb protein did not correlate with the severity of the disease. At the transcriptome level, the studied lines responded to the pathogen treatment individually in the first sampling (10 days) whereas the expression profiles of the lines resembled each other in the second sampling (21 days). The functional grouping of the genes with known mode of action resulted most representative in protein metabolism, photosynthesis, stress as well as RNA metabolism groups. In general, the transcriptome profiling of fungicidal and herbivory-induced responses did not reveal any biological or molecular process altered in all of the VHb lines due to the biotic interactions. Moreover, based on the real-time RT-PCR results, the VHb expression did not show induction after the 24-hour herbivore treatment or the inoculation with the V. tremulae.

Increased *Bacillus thuringiensis* δ-endotoxin Cry3Aa toxicity against longhorned beetle by fusing to peptide specifically binding to beetle Cx-cellulase

Shi-Tang Zhao1,*, Chang-Hua Guo1, Jian-Jun Hu1, Xiao-Jiao Han2, Jun Chen1, Meng-Zhu Lu1
1State Key Laboratory of Forest Genetics and Tree Breeding, Research Institute of Forestry, Chinese Academy of Forestry, Beijing 100091, PR China; 2International Centre for Bamboo and Rattan, Beijing 100102, PR China
E-mail: shutang@caf.ac.cn

**Background:** *Bacillus thuringiensis* (Bt) Cry toxins have specific toxicity to susceptible insects. They are being used in transgenic plants or spray to control insect pests in agriculture [1, 2, 3]. Cry3A toxins are used extensively for biological control of coleopteran larvae [4, 5]. A Bt886-Cry3Aa gene that exhibited a high activity against Coleoptera insects isolated Our laboratory. Insect bioassay performed on *Anoplophora glabripennis* Motsch and *Apriona germari* Hope showed that the mortality of larvae fed with the product of this gene was over 60% [6]. However, both transgenic poplar with native Cry3Aa and with modified-Cry3Aa by using poplar-preferred codons did little effects on longhorned beetles probably due to its low expression level in poplar. A peptide (LPPNPTK) named PCx that specifically bind to cellulase from midgut of longhorned beetle larvaes was screened out from a phage display library previously in our laboratory [7].

**Materials and methods:** Fused Cry3Aa genes with PCx coding sequence at 5’ or 3’-end were amplified using pET-30a (+)-Cry3Aa [6] as a template and designed primers, and, used to construct three recombinant plasmids (pET-30a (+)-PCx-Cry3Aa, pET-30a (+)-Cry3Aa-PCx and pET-30a (+)-Cry3Aa). Target proteins were characterized by Western Blot, ELISA and LC-MS/MS methods. To analyze the activity of PCx-Cry3Aa, Cry3Aa-PCx and Cry3Aa proteins against longhorned beetle larvae, bioassays were performed on *A. germari*Hope larvae by artifical feed with toxins. The retaining time of target proteins in midgut and the cellulase activity of longhorned beetle larvae were measured in order to elucidate the potential mechanism of the fused toxins of PCx and Cry3Aa against longhorned beetle larvae.

**Results:** Expression products contained target proteins were characterized by SDS-PAGE, Western-blot and ELISA after induced by IPTG. The target bands were digested and analyzed by LC-MS/MS to further confirm them as Cry3Aa proteins. The bioassay showed that the mortality of larvae fed with the two fused Cry3Aa proteins (PCx-Cry3Aa and Cry3Aa-PCx) was up to three times higher than that fed with Cry3Aa (Figure 1). Retaining time analysis was performed on excretas that collected at different times after feeding. The result showed that the fused Cry3Aa was concentrated in excreta collected at 6 h, whereas Cry3Aa at 4 h. Meanwhile, the Cry3Aa concentration in mid gut juice after fed with fused Cry3Aa was higher than that with cry3Aa alone. This indicated that the retaining time of fused PCx-Cry3Aa in mid gut of larvae was longer compared to that of Cry3Aa alone (Figure 2). In addition, we also analyzed the cellulase activity when bond with fused Cry3Aa or Cry3Aa alone and showed that the fused protein did not affect the activity of cellulase. Therefore, the remaining time of fused Cry3Aa is prolonged after binding with cellulase, thus the enhanced toxicity of fused Cry3Aa is due to the prolonged retaining time.

**Conclusions:** These data demonstrate that the cellulase-binding peptide could enhance the toxicity of *Bacillus thuringiensis* Cry3Aa against the longhorned beetle. We also confirmed that the increased lethality in larvae fed with PCx-Cry3Aa or Cry3Aa-PCx was attributable to the ability of the toxin to bind Cx-cellulase, thereby increasing toxin retention in the midgut. These uniquely modified Cry3Aa proteins have potential use for pest control. The significantly enhanced activity of Cry3Aa fused with the Cx-cellulase-binding peptide provides a new strategy for increasing δ-endotoxin efficacy against the longhorned beetle.

**Figure 1** (abstract P89). Toxicity of Cry3Aa and the Cry3Aa fusion proteins against *A. germari*Hope larvaes. Corrected mortality rates are shown for larvaes fed with Cry3Aa, PCx-Cry3Aa or Cry3Aa-PCx. Both Cry3Aa fusion proteins exhibited increased toxicity toward the larvaes, compared with non-modified Cry3Aa.

**Figure 2** (abstract P89). Concentration of Cry3Aa in *A. germari*Hope larvaes after feeding with Cry3Aa and the Cry3Aa fusion proteins. a, Cry3Aa was measured in larval excretions collected at 2, 4, 6, and 8 h after feeding. The Cry3Aa content peaked at 4 h after feeding with Cry3Aa, whereas the peak was observed at 6 h after feeding with the Cry3Aa fusion proteins. b, Cry3Aa was measured in larval mid gut extractions at 4 h after feeding. The concentration of Cry3Aa in the mid gut extracts was higher after feeding with the fusion proteins, compared with non-modified Cry3Aa.
Metrology of morphological response of Siberian elm to drought stress: increased stomatal pore depth

Ki Woo Kim1*, Go Eun Park2, Don Koo Lee2

E-mail: kiwoo@knu.ac.kr

Background: Structural characteristics of stomata consist of stomatal shape, density, depth, and pore dimension. Commonly called Siberian elm, the species Ulmus pumila L. is a fast-growing and small to medium-sized tree. Due to the superb adaptations to the harsh conditions of the Gobi Desert, the trees have been preferentially planted in Mongolia. It is worthwhile to investigate the morphological characteristics of the tree species that are tolerant to drought stresses in such arid areas.

Materials and methods: Based on average annual precipitations, two types of leaf specimens were collected from Korea, China, and Mongolia: (i) leaves under normal environmental conditions and (ii) leaves under arid conditions. Leaf stomatal characteristics of Siberian elm were investigated by electron microscopy and white light scanning interferometry [1].

Results and conclusions: Field emission scanning electron microscopy revealed stomata on the lower leaf surface of the tree species. Measured as ca. 30 micrometers in width, the stomata appeared to be oval in shape. In-lens secondary electron imaging by a coaxial annular type detector showed a difference in depth from epidermis to pore between the two types of leaves. Leaf stomata under arid conditions appeared to have higher levels of depth from epidermis to pore than ones under normal conditions (Figure 1). Line profile analysis by white light scanning interferometry allowed for the nondestructive measurement of the stomatal dimension (Figure 2). The depth from epidermis to pore of stomatal complexes under normal conditions was ca. 1.79±0.13 micrometers, whereas that under arid conditions was ca. 2.12±0.08 micrometers. In addition, higher levels of surface roughness were observed in stomata under arid conditions than those under normal conditions. These results suggest that increased stomatal pore depth would be responsible for the adaptations of the tree species to arid conditions. Furthermore, such architectural differences in

Figure 1 (abstract P90) Field emission scanning electron micrographs of stomata of Siberian elm. (A) Stoma under normal conditions. (B) Stoma under arid conditions.

Boron is a micronutrient that plays an important role in plant cell wall biosynthesis. Nevertheless, an excess of boron in the soil causes severe damage to the respiratory tissue of the plant. In Arabidopsis thaliana, the Atbor1 gene encodes a boron transporter that distributes this element throughout the plant.

A cDNA sequence encoding a bor1 transporter was isolated from a Eucalyptus globulus cDNA library. This sequence contains several stop codons within the coding region. Initial bioinformatic analyses suggest that this interruption corresponds to an intron that may generate a truncated protein.

Egbor1 was overexpressed in Saccharomyces cerevisiae to assess whether it was capable of restoring the phenotype of a mutant strain that lacks the boron transporter. It was also overexpressed in a wild type strain as a control. In both cases a significant increase in boron tolerance was observed, suggesting that the encoded transporter is functional. Subsequently, a western blot analysis showed that the expressed transporter corresponds to the product of the full-length protein, rather than the truncated protein.

Additional bioinformatic analyses showed that the intron presents several regulatory elements, therefore it may function as a promoter for a small protein encoded in the 3’ region of Egbor1. Transient expression of GUS under the control of the intron sequence proved its capability to activate gene expression. Thus, we have identified three ORFs in the Egbor1 sequence: a full length protein encoded by the spliced mRNA named fragment C, and two smaller proteins encoded by the 5’ and the 3’ regions of the non spliced mRNA named fragments A and B.

We are currently challenging the yeast mutant strain with all the putative encoded proteins to understand their specific role in boron transport. Funded by PFB-016 and DI-UNAB.

BMC Proceedings 2011, 5(Suppl 7):P92

Background: Japanese pine trees have been severely damaged by the pine wilt diseases, and hardly been keeping the productive forest in Japan. The pine wood nematode, Bursaphelenchus xylophilus, is a virulent pathogen in Japan, while it is originated and is an endemic one in the United State [1]. The diseases have now been spread not only in East Asia but also in a part of Europe. The Japanese Government has been developed the resistant pine breed varieties which had selected the survived-tree lineages obtained from the damaged pine forests. The developed varieties vary in the disease severity depending on the individual trees even in the same variety, partly because of the wind-pollination. Thus it needs molecular indices to select the resistant individuals without nematode infection.

Shin et al. [2] reported up-regulated genes in a non-selected, or susceptible, Japanese red pine, Pinus densiflora, after the nematode inoculation. Defense responses distinct from the susceptible trees may be expressed in the resistant bleed variety against the pine wood nematodes. By comparing the expressed gene profiles between the resistant and susceptible varieties against the diseases, a molecular clue for the resistant response against the diseases will be provided. Here, we have compared gene expression profiles between the susceptible and resistant breed varieties of Japanese red pine at the stage when the defense response had
just established after the nematode inoculation. We also discuss on the gene components involved in the disease severity or resistance.

Methods: Pine wood nematodes were inoculated on 2-year-old seedlings of a non-selected susceptible and one of the strongest resistant breed variety, respectively. The five samples were harvested at every 7 days and counted the nematode numbers of the samples. They are also stored at -80°C for RNA extraction. The nematodes were collected by Baermann funnel technique and counted under a stereomicroscope to judge the resistance. RNAs were extracted from the resistant and susceptible stems and judged at the stage when the nematodes had just started to propagate, by using the range of sensitive and resistant breed varieties, were effectively sequenced and assembled as the contigs. They were subjected to Blast retrieval against various public databases for their assignments. The data sets obtained were analyzed in silico.

Results and conclusions: A contig sequence is composed of ESTs, and it approximates an expressed gene species, while the numbers of ESTs in a contig approximate the expressed level of the gene. Comprehensive expression analyses show that the contig numbers, i.e. gene species, were more abundant in a resistant breed variety than those in a susceptible one. The contigs expressed more than 4 ESTs, being composed of 803 ESTs, were three times abundant in the resistant variety than in the susceptible one. The defense response might be triggered by the nematode invasion in a resistant variety but not in a susceptible one. Alternatively, it may be caused by the suppressed gene expression in the susceptible one. The latter is more probable because the signal transduction involved in the resistant response had blocked in the susceptible variety (Figure 1). The flavonoid biosynthesis had been transcriptionally more expressed in the resistant variety than in the case of the susceptible one. One of the authors had suspected that nematocidal stilbenoids, which are abundantly localized in pine heartwood, might be involved in the disease resistance [3]. The stilbenoid biosynthesis was activated by methyljasmonate or salicylate application but did not detect in this experiment at the stage when the resistant variety just had established defending response. The phenolic metabolites were more produced in the resistant variety comparing to the case of the susceptible one, supporting the results from the transcriptional observation. Some pathogen related (PR) proteins were not observed in the resistant breed but were up-regulated in the susceptible one, suggesting such proteins may be induced by stress and not directly involved in the defense response. A cluster, being composed of the contigs, approximates a gene family and represents a hot spot in the mutation which may or may not be involved in the defense response. We will also discuss those gene families.

Acknowledgements: The authors are deeply expressed their thanks to Dr. Ohhira, M. and Dr. Fujisawa, Y. of Forest Tree Breeding Center, FFPRI, for their kind supply of shoots of a resistant variety after the nematode infection. The study was supported by the grants from ISS, Kyoto University and also from the JSPS for HK.

Background: Jatropha curcas is a drought resistant shrub native in tropical America, now widely grown in many tropical and subtropical regions for biodiesel production [1]. First reports on virus infections in Jatropha indicated the occurrence of viruses closely related to Cassava mosaic virus in India, reaching a disease incidence from 25 to 47%. This might represent a major constrain to the production of Jatropha in large scale [2]. The three samples of Cassava mosaic geminiviruses (CMG) consist of two components termed DNA A and DNA B (~ 2.7 – 3.0 kb) [3]. Furthermore, Jatropha has been described as host of Cucumber mosaic virus (CMV) [2].

Methods: In this study we attempted to detect and molecularly characterize viruses infecting Jatropha in Eastern Africa (Kenya and Ethiopia). Detection methods will be valuable tools for early screening of plant varieties in order to make appropriate decisions and selection of planting material. A total of 127 Jatropha samples from Ethiopia and Kenya (districts: Kakamega, Siaya, Busia and Nakuru showing typical virus symptoms and symptomless plants were used in this study. ELISA was performed to detect the presence of three RNA viruses: CMV, Cassava common mosaic virus (CCMV) and Cassava brown streak virus (CBSV). PCR was performed using newly designed primers based on multiple alignments of full length DNA A sequences of geminiviruses available in the NCBI Genbank, reported to infect either Jatropha or cassava. This allowed to amplify the variable regions of full length (2800 bp) and shorter sequences (380-1085 bp). PCR primers were sequenced and phylogenetic trees were constructed from multiple alignments by performing a heuristic search. Multiple alignments were analyzed by maximum parsimony with full-length DNA A using Phylogenetic Analysis Using Parsimony (PAUP) and a bootstrap analysis with 1000 replicates.

Results and conclusions: None of the Jatropha samples analysed was infected with the RNA viruses CBSV, CMV and CCMV. PCR primers amplifying a 380 bp fragment of Ac1, Ac2 and Ac3 yielded positive results with 75% of the symptomatic samples from Kenya and further detected 20% of asymptomatic samples as positive. Furthermore, 61% of symptomatic Jatropha samples from Ethiopia were positive. Full length primers were able to detect 69% symptomatic Jatropha samples from Kenya, and also in 67% of asymptomatic samples. PCR analyses of sample KUJS amplified the expected 2.8 kb of a near full length DNA A component of the Begomovirus sequence and an additional shorter fragment. Complete nucleotide sequences of 34 DNA A components typical of Begomoviruses were determined in the Kenyan samples. Thirty three sequences ranged from 2770 bp to 2816 bp while one (K1JS) consisted only of 1416 bp and termed as a defective (Def) DNA. Phylogenetic analyses indicated that the defective molecule belongs to geminiviruses involved in CMG, representing a Def from DNA A of the bipartite Begomovirus ACMV. All viruses characterized in this study grouped with two previously identified Begomoviruses found in cassava in Western Kenya, namely EACMV – UG and ACMV. The Def DNA showed 96.6% sequence identity with the ACMV reference sequence [GenBank NC001467].

Results of the first time the detection of Begomovirus: EACMV and ACMV – UG in Jatropha from Kenya. From an evolutionary perspective, the phylogenetic data indicate that the virus isolates from the study were closely related to those isolated previously in Western Kenya from cassava [4,5]. Recombination and synergism that have long occurred in cassava could have had a recent spread of the virus in the field to infect Jatropha. Presence of EACMV – UG and ACMV on Jatropha plants in the same field indicates the opportunity for mixed infections, hence offering good opportunities for more recombination to occur. EACMV – UG and ACMV are associated with severe synergistic epidemics on cassava. Synergism lead to a 10 - 50 fold increase in viral DNA accumulation which substantially increases the potential for a higher efficiency of vector transmission to even infect non cassava host plants [6,7]. This explain why EACMV - UG is the predominant virus in Jatropha. The deletions occurring in the Def DNA found in the study might affect the replication of the molecule and it might depend entirely on its helper virus for replication. There is a possibility of Cassava mosaic virus in Jatropha being more widespread than anticipated, since we have detected it also in Jatropha samples from Ethiopia.

CIC-Buenos Aires E-mail: vluquez@agro.unlp.edu.ar

**BMC Proceedings 2011, 5(Suppl 7):**P94

**Background:** In Argentina, most poplar plantations are located at the Paraná River Delta. Climate change models indicate an increase of flooding events for the next decades in this area. Therefore, poplar genotypes with a higher flooding tolerance will be needed for the forest activity. Whether this aim is achieved through traditional breeding or biotechnological developments, it will be important to gain a better understanding of poplar responses to flooding at physiological, biochemical and molecular levels.

In a previous work, we characterized the growth and morphological responses of several poplar clones to 35 days of flooding of the root system [1]. From this group, we selected two Populus deltoides clones with different growth responses to flooding: Alton and Stoneville 67. In clone Alton, above ground growth is not affected by flooding, while in Stoneville 67 growth is reduced after the second week of flooding. In the present work, our aim was to identify mechanisms underlying the differences in growth responses to flooding between the two clones. We characterized physiological and biochemical responses in roots and leaves, during a flooding period of 28 days, followed by an after flooding period of three weeks.

**Materials and methods:** Two Populus deltoides clones were used, Alton and Stoneville 67. Plants were obtained from 20 cm length one year old cuttings. The cuttings were planted in 3.5 L pots filled with a mix of topsoil and sand 50:50, and grown in a greenhouse in a totally randomized design; pots were watered daily to field capacity until the start of the treatment. The flooding treatment was started when the plants reached 50 cm of height. Flooding was imposed by covering the pots with tap water up to 5 cm over the surface soil, during 28 days, after this flooding was ended and pots previously flooded were removed from the water and left to drain. Growth in height was measured weekly with a graduate stick. Stomatal conductance was measured in the last expanded leaf with a Decagon SC1 porometer. Electrolyte leakage was measured in root tips. Samples were taken from leaves and roots to measure oxidative damage by thiobarbituric acid reactive substances (TBARS) method and enzymatic and non-enzymatic antioxidants. Leaf discs were taken from the last expanded leaf to measure protein content using the Bradford method. This destructive sampling was carried on in the following dates: day 0 (before the start of flooding); 2 weeks after the start of flooding, 4 weeks after the start of flooding; 1 day after the end of flooding, and 1, 2 and 3 weeks after the end of the flooding.

**Results and discussion:** After 28 days of flooding, growth in height was reduced 14% in flooded plants of Stoneville 67 compared with non-flooded control plants, but it was not affected in Alton. This was a lasting difference; three weeks after the end of flooding the height of previously flooded Stoneville 67 plants still was 15% lower than the control plants. Stomatal conductance was reduced by flooding in both clones, but in Stoneville 67 to a greater extent: 81% compared with only 63% in Alton. The recovery of the stomatal conductance to the control levels after flooding was slow and occurred only after two weeks, and was faster in Alton than in Stoneville 67.

**BMC Proceedings 2011, 5(Suppl 7):**P95

**Growth habit and developmental phase transitions in plants are acutely responsive to the quantity and quality of incident light. Information about neighbouring plants is primarily perceived by changes in the light environment. Arabidopsis is able to distinguish these changes through the phytochrome (PHYA-E) red light receptors that perceive changes in the red to far red (R:FR) ratio, and the cryptochrome and phototropin blue light receptors. Phytochrome, in its biologically active far-red-light absorbing form (Pfr), mediates its effects by directly binding with the basic helix-loop-helix (bHLH) phytochrome-interacting factors (PIFs). High R:FR ratios initiate phytochrome (Pfr)-PIF binding and PIF protein degradation. Low R:FR ratios photo-convert Pfr into the inactive form Pr**
allowing the gene expression that leads to a range of adaptations, including the shade avoidance responses. PIF1 regulates the expression of a number of genes by directly binding to a G-box element in their promoter. T-DNA insertional mutagenesis of a number of these genes results in pleiotropic effects associated with an altered capacity to respond appropriately to environmental cues, including those signalling changes in soil water status and the ambient light environment. The data show evidence of a perturbation of light regulated response processes, including germination, the shade avoidance responses, stomatal conductance, flowering and the circadian clock perturbation in the PIF-regulated gene mutants. The pif1,3,4,5 quadruple and one of the PIF-regulated gene mutants fail to show shade avoidance responses in older plants grown under shade inducing conditions. This suggests that the encoded proteins mediate a parallel pathway in the induction of the SAS. The implications of our findings for an understanding of how plants appropriately respond to changes in their environment will be discussed.

Expression profiling of putative Eucalyptus grandis defence marker genes in response to treatment with methyl jasmonate and salicylic acid

BMC Proceedings 2011, 5(Suppl 7):P96

Background: Eucalyptus species and their hybrids encompass approximately 40% of forestry plantation area in South Africa and contribute significantly to the paper pulp industry due to their favourable wood fibre properties. Eucalypt plantation trees are affected by numerous pathogens during their lifetime, some of which can cause severe losses such as Phytophthora spp and Chrysoporthe spp. Plant defence mechanisms against pathogens is currently better understood in the model plant Arabidopsis thaliana where it has been shown that the salicylic acid (SA) and jasmonic acid (JA) signalling pathways enhance resistance against biotrophic and necrotrophic pathogens, respectively [1]. This process involves the up-regulation of specific defence genes which are considered to be marker (diagnostic) genes for the two signalling pathways [2,3].

Methods: The aim of this study was to utilize the draft (8X) E. grandis genome sequence that has recently become available (http://eucalyptusdb.bi.up.ac.za) to identify Eucalyptus orthologs of defence marker genes (e.g. PR2; PR3; PR4; PR5; LOX2) specific for the SA and JA signalling pathways [2,3]. Bioinformatics tools were used to identify putative orthologs of these marker genes in E. grandis based on sequence information from other plants. This was followed by a co-phylogenetic analysis in which a neighbour-joining tree with 10 000 permutations was constructed to add confidence that the correct orthologs had been identified. In the phylogenetic tree analysis, closely related family members of a particular gene were added to increase the certainty and accuracy of selecting a specific ortholog. The expression profile of the putative marker genes was assessed via Reverse Transcription quantitative PCR (RT-qPCR) analysis of transcript levels following treatment with various concentrations of the inducers (SA and JA) as well as different time points. This was done to confirm that the putative orthologs respond to the appropriate pathways in Eucalyptus. Additionally the expression profile of these putative orthologs was analyzed in response to the causal agent of Eucalyptus stem canker, Chrysoporthe austroafricana. The defence response of Eucalyptus to this necrotrophic pathogen was investigated in both a tolerant (EgrTOL) and...
susceptible (EgrSUS) species. Changes in the level of transcript expression of the putative marker genes (PR2; PR4; PR5; LOX3) were assessed at three time points using RT-qPCR.

**Results and discussion:** A dose response experiment of the putative marker genes was conducted with various concentrations to elucidate which would elicit the most paramount response in gene expression. It was found that amongst the tested candidates, 5mM and 100μM displayed the most significant change in gene expression for SA and JA respectively (Table 1). The specificity of the putative markers was also determined by profiling the putative marker genes with material induced by the opposing pathway, i.e SA markers were assessed with MeJA induced material.

A time course experiment was done to investigate how the expression profiles of the genes respond over a period of time. This would shed light on a possible window period that one could focus on for enhancing resistance as the timing of defence is crucial in determining the outcome of a pathogen interaction. For example the PR2 gene, a marker for the SA pathway, was shown to be drastically induced at 24hrs followed by a decline at 48hrs. This could be due to the fact that high levels of SA are toxic to the cell so the plant needs to closely monitor SA levels. On the other hand PR4, a marker for the JA pathway displayed a gradual increase over time beginning at 6hrs and peaking at 48hrs.

When the putative marker genes were assessed in tissue infected with *Chryso horrible* it was observed that role of SA could potentially have a crucial role in determining the outcome of the infection. It is interesting to note that at two weeks there is no significant difference in lesion length between EgrSUS and EgrTOL. In EgrTOL, the expression level of PR2 was significantly up-regulated at two weeks post-inoculation whereas EgrSUS had significantly altered levels of expression only at six weeks. However in EgrSUS, the level to which PR2 is induced is still lower than in EgrTOL. At two weeks and six weeks there is an increase in PR4 transcript levels in EgrSUS. This could explain the inability of EgrSUS to accumulate SA due to the antagonistic relationship between the two pathways which is in accordance to what is currently known in Arabidopsis [1].

**Conclusion:** The genes identified in this study were tested as a diagnostic tool for the screening of pathogen challenged eucalypt plant to determine which signaling pathway(s) were playing a role in defence against various pathogens. It was found that SA could potentially play a role in enhancing resistance to *C. australaficana*. Future work would involve studying the expression profile of these genes in response to various other pathogens as well as to elucidate more putative marker genes. This research provides a platform from which to expand our knowledge of plant defence in *Eucalyptus* and work towards curbing tree diseases.

**P97 Investigating Eucalyptus – pathogen and pest interactions to dissect broad spectrum defense mechanisms**

Sanushka Naidoo1, Ronishree Naidoo, Caryn Oates, Febe Wilken, Alexander Myburg

FABI, University of Pretoria, South Africa

E-mail: sanushka.naidoo@fabi.up.ac.za

**BMC Proceedings 2011, 5(Suppl 7):P97**

**Background:** Eucalyptus species, hybrids and clones are attacked by various fungal and bacterial pathogens and pests during their life-time. Global climate changes are predicted to create favourable environments for such pathogens and pests and increase incidence of host jumping from other crops, resulting in increased losses to the forestry industry [1]. The use of tolerant or resistant plant varieties as part of an integrated disease management strategy is recognised as a desirable means to curb disease incidence. Vertical resistance mediated by resistance (R) genes, may be easily overcome by a pathogen and is thus not adequate on plantation species such as Eucalyptus, which would be exposed to various pathogens during its life-time. Broad spectrum resistance on the other hand, would be desirable to provide resistance against multiple challenges [2].

The aim of this study is to investigate mechanisms involved in host resistance with an emphasis on broad-spectrum resistance. The availability of the complete genome sequence of *Eucalyptus grandis* (http://www.eucagen.org) and the transcriptome sequence of a *E. grandis* X *E. urophylla* (GU) hybrid [3] has provided resources to investigate defense responses in the natural host. When a pathogen attacks a plant, the plant launches a sophisticated defense response involving phytohormones such as salicylic acid (SA), methyl jasmonate (MeJA) and ethylene (ET). These responses are finely tuned and tailored to the invader [4]. Down-stream of the signalling cascade is the production of pathogenesis related (PR) genes and antimicrobial genes which serve to limit the pathogen and afford protection. PR genes, such as PR-1 and PR-5, are known markers of the salicylic acid defense pathway, while PR-3, PR-4 and the lipoxigenase (LOX) genes are known markers of the MeJA and ET signalling pathways. The discovery of PR genes in *Eucalyptus* is desirable as these genes have previously been shown to afford broad spectrum resistance in other crops. We present our progress in exploiting the *Eucalyptus* genominc and transcriptomic data for the discovery of tree defense genes and explore the application thereof in determining which pathways are activated in response to various pathogens.

**Materials and methods:** Infections and infestations: *E. grandis* clones were treated with *Chrysosporthe australaficana* in the following manner: wounds were created using a 0.3cm cork borer to expose the cambial tissue and an agar plug containing fungal mycelia were applied to the wound and sealed with parafilm. As a control, plants were mock inoculated. *E. nitens* plants were inoculated with *Phytophthora cinnamomi* using a 0.3cm cork borer, and a mycelial plug applied. The wound site containing the pathogen was sealed with moist cheese cloth and parafilm. A set of plants received no inoculum. *E. grandis* clones were maintained in the FABI nursery and were naturally infested with *Leptocybe invasa*. A set of plants were maintained under similar conditions but were not exposed to the insect pest.

**Expression analysis:** RNA was harvested from from stem tissue (from *C. australaficana* and *P. cinnamomi* interactions) and leaf tissue (for *L. invasa* interactions) at two time points after challenge in order to detect early and late responses. RNA was isolated using the CTAB method [5] and cDNA synthesized. Reverse transcriptase quantitative PCR (RT-qPCR) was performed using the Roche 480 LightCycler instrument.

**Results and discussion:** Reliable pathosystems were established for *Eucalyptus* with *P. cinnamomi* and *C. australaficana*. Figure 1A and 1B show the lesions which developed after pathogen challenge compared to mock inoculated plants. Figure 1C shows the results of natural infestation of young leaves of *E. grandis* clones under nursery conditions compared to plants not exposed to the pest. The oviposition sites are evident on the leaf midrib (indicated by the white arrow). Using a bioinformatic and phylogenetic approach, the putative orthologs for PR-1, PR-2, PR-3, PR-4 and PR-5 were identified. The basal expression level of PR-3 in the GU hybrid transcriptome is indicated in Figure 2 as an example.
The high basal expression of PR-3 in the GU hybrid may indicate that the MeJA and ET pathway is activated in this genotype. PR-3 genes are chitinases, enzymes that are able to hydrolyze chitin, a component of fungal cell walls [6]. Further expression profiling of the diagnostic marker genes for the two main defense pathways during C. austroafricana challenge suggests that the SA pathway is important for defense against the pathogen in the tolerant interaction.

Conclusions: We have established important pathosystems between Eucalyptus and a fungal pathogen, Eucalyptus and an oomycete pathogen and between Eucalyptus and an insect pest. Genes diagnostic of the main defense signaling pathways between Eucalyptus and a fungal pathogen, Eucalyptus and an oomycete pathogen and between Eucalyptus and an insect pest. Genes diagnostic of the main defense signaling pathways have been identified and are being exploited to determine which pathways are activated in tree-pest/pathogen interactions. It is expected that transcriptome sequencing of each of these interactions will not only reveal the suite of genes important for defense against specific pathogens and pests, but the overlap of the responses at the molecular level, would be informative for broad spectrum resistance. These genes are potential future candidates for genetic improvement of disease tolerance in eucalypts.

Background: Eucalyptus is grown in around 3.9 Mha in India. Leptocybe invasa Fisher & La Salle (Hymenoptera: Eulophidae) has emerged as a serious pest in Eucalyptus causing considerable loss of quality planting materials besides loss in productivity and quality of timber. Current strategies for its control include selected deployment of Eucalyptus clones tolerant to the pest resulting in several productive Eucalyptus genetic
resources, not being considered for plantation programmes, as in the case of the widely planted Eucalyptus clone, ITC 10, and ITC 271. The securely ensconced grub within the gall for a period of around 4 months post oviposition makes it refractory to pesticide applications. This feature, however, makes plant- incorporated protectants, via RNAi approaches a potential strategy for engineering resistance [1-3]. However, application of RNAi technology requires determination of sequence information of insect-specific genes so that off-target effects in plants as well as human beings are avoided.

**Methods:** Grubs were collected from the galls of *E. camaldulensis* clones, APNP 1.1 and ITC 351, infested with *L. invasa* from the nursery of the Institute of Forest Genetics and Tree Breeding, Coimbatore, India. Genomic DNA was isolated from the grubs homogenized in liquid nitrogen using a modified CTAB protocol [4]. RNA was isolated from the grubs using Qiagen RNeasy plant mini kit, followed by cDNA synthesis using SmartScribe reverse transcriptase. Grubs were also directly used for PCR amplification circumventing DNA isolation. Furthermore, to enable multiple PCR analysis, a single grub was collected into 50 μl of sterile distilled water, vigorously vortexed for 2 min followed by brief denaturation at 95°C for 10 min and centrifugation at 10,000 rpm for 10 min. The supernatant was used for PCR analysis.

The PCR mix consisted either 100 ng genomic DNA or 100 ng cDNA or a single grub or 2 μl of supernatant from denatured grub, in 1X PCR buffer, 0.8 mM dNTPs, 1 μM of each primer, 2.5 U *Pfu* polymerase (Fermentas). The PCR conditions used were initial denaturation at 94°C for 5 min, cycle denaturation at 94°C for 40s; annealing at 60°C for 40s; extension at 72°C for 2 min for 30 cycles, and a final extension of 72°C for 5 min. In case of grub PCR, initial denaturation was for 10 min at 95°C. The PCR products were resolved on a 1.0% Agarose gel in 1X TAE. When multiple bands were obtained, the products were gel eluted and either directly sequenced or cloned into pGEMTeasy vector prior to sequencing. Sequencing was done using the ABI PRISM 3130 XL Genetic Analyzer using Big Dye Terminator version 3.1 Cycle sequencing kit through the commercial sequencing services available at Chromous Biotech India Pvt Ltd.

**Results and discussion:** Chitin synthase gene was partially amplified using the degenerate primer sets, CSF3 (5'-TGYGGCGAHA TGTGGGACARAC-3')/CSR1 (5'-GTCCTCSCCYT GRTCGTAYTGCAC-3') and CSF1 (5'-YTGGAY GGGMGACATMGAYTTC-3')/CSR1 (5'-GTCTCSCCYT GRTCGTAYTGCAC-3')[5] from genomic DNA and cDNA. CSF3/R1 primers yielded multiple bands of which the expected 1KB size amplicon was sequenced. CSF1/R1 primers yielded an amplicon of 370 bp, which overlapped with the sequence from CSF3/R1. The sequence data obtained were aligned, annotated, and a sequence of 624 bp was submitted to NCBI (Accession number: JF772551/ to be published). The sequence comprising 2 exons and 2 introns, corresponded to 138 amino acids on conceptual translation. BLAST analysis of the nucleotide sequence showed 85% homology to *Nasonia vitripennis* chitin synthase 1 and 76% to *Apis mellifera* krotzkopf verkehrt (chitin synthase1) sequences. Furthermore, a rapid method of PCR amplification directly from grubs was developed. The amplicons generated using the primers CSF1/CSR1 yielded the same sequence, indicating its utility for rapid PCR screening of *L. invasa* grubs. In order to identify housekeeping genes for use as reference genes during quantitative PCR analysis, Elongation factor-1 alpha (EF-1 alpha) was partially amplified using primers EF1-F (5'-GATATCGACAAAA CGT ACCATGC-3')/EF1-R (5'- AATCGGACAGCAAGG TGGTAAACC-3') and the sequence data of 534 bp was submitted to NCBI.
Gene expression responses of black spruce (Picea mariana) to global climate change conditions

Om Rajora1, Jinhong Kim1, John Major2, John Malcolm2

1Faculty of forestry and environmental management, University of New Brunswick, 2Dineen Drive, Fredericton, Nb E3B 5A3, Canada. 2Natural Resources Canada, Atlantic Forestry Centre, 1350 Regent Street, Fredericton, Nb E3B 5P7, Canada. E-mail: Om.Rajora@unb.ca

Global climate change conditions (elevated CO2 and atmospheric temperatures) are subjecting our forests, especially boreal and temperate forests, to significant biotic stresses, such as drought. This can affect health, productivity and fitness of our forests. Therefore, it is imperative to understand genomic and eco-physiological responses of forest trees to global climate change. We are addressing this aspect in black spruce (Picea mariana) - a transcontinental, ecologically and economically important tree species of the North American boreal forest. Our objective was to determine gene expression and physiological responses and their inter-relationships in black spruce to elevated CO2, drought and combined stress conditions.

We have used NGS whole transcriptome sequencing, cDNA-AFLP and qPCR analyses to identify, annotate and characterize genes expressed differentially in response to elevated CO2, drought and combined elevated CO2 and drought conditions in black spruce using the cloned material. Photosynthetic rate and stomatal conductance were measured simultaneously with tissue collection for RNA extraction. Thousands of transcripts (genes) showed differential expression (no expression, up-regulation or down-regulation) in response to elevated CO2, drought and/or their combined conditions, with over 1600 genes from several pathways showing >10-folds gene expression differences between control and treated plants. A number of genes showed 100 to 500 folds up or down regulation in response to elevated CO2, drought or their combined conditions. Responses to each treatment at the gene expression and physiological levels were correlated well among different genotypes. We will present these results which contribute significantly to our understanding of tree's responses to global climate change.
showed a carbon accumulation between 221.3 and 235.9 Mg C ha\(^{-1}\) and in the roots, the carbon accumulation is in the range between 35.7 and 48.3 Mg C ha\(^{-1}\).

These results indicate that carbon stored in aboveground biomass appeared to represent the main carbon pool of tree biomass and that resin tapping had minor impact on C allocation in wood biomass, considering the time frame and stand age examined. Further studies and sampling times are ongoing in order to better characterize carbon stocks in subtropical slash pine plantations and to elucidate the contribution of oleoresin production in carbon stocks and its relation with C in wood biomass.

BMC Proceedings 2011, 5(Suppl 7):P101

Background: The defoliation of oaks is an urgent problem for forestry in Central Europe. During the last outbreak of the green oak leaf roller (Tortrix viridana) in 2003-2005, we observed fundamental differences in the defoliation level of individual Quercus robur trees in Germany. Some of the trees seem to be somehow "tolerant" (T oaks) against the insects grub while some seem to be conspicuously "susceptible" (S oaks). Within this study we aim to identify the underlying molecular and biochemical mechanisms in oaks responsible for the behavioural preference of T. viridana. By means of combined behavioural experiments and biochemical as well as molecular analysis of preformed and induced defence mechanisms in T and S oak phenotypes, we will identify the metabolic/chemical basis of the observed differences as prerequisite for the selection of candidate genes differentially expressed in tolerant and susceptible trees, respectively, after insects feeding.

Methods: For this purpose we until now grafted each four of the identified T and S oaks, and used them for our further experiments. The methods used at this time are as following:
1. Establishment of a "bioassay": Larvae of the green oak leaf roller have been tested for feeding preferences on T or S oaks in a feeding choice experiment. Furthermore first olfactometer experiments with adult females were performed and the developmental performance of the larvae has been measured.

2. Preliminary analysis of emission pattern of plant volatile organic compounds (VOC) during the bioassay on T and S oaks has been done. Biochemical analysis of phenolic compounds (e.g. tannins, soluble phenolic substances) and constitutive and inducible emissions of plant volatiles in T and S oaks during relevant stages of leaf ontogeny and insect feeding and oviposition are ongoing.

4. Transcriptomic sequencing of T and S oaks: Overall gene expression differences between the T and S oaks have been tested using biochemically defined leaf material harvested after the bioassay by next generation sequencing analysis of the complete mRNA (transcriptom). Candidate genes involved in the defence response of oaks will be identified and compared to differences in constitutive and induced patterns of phenolic compounds and VOC emissions. Results: We will present preliminary results of the following aspects of our study:

1. Feeding choice experiments with larvae of Tortrix viridana: The larvae had the choice between a leaf from T-oak and a leaf from S-oak. After 24h, the time of feeding at each leaf was documented. We found a significant preference of the larvae for the leaves from S-oaks.

2. Olfactometer experiments with adult females: Adult paired moth had the choice between a drafted T- and S-oak in an olfactometer. After 30 minutes the decision of the moth was documented. A highly significant number of females chose the S-oaks instead of the T-oaks.

3. Performance experiment: Larvae had been fed with leaves of either S- or T-oaks only. The larvae fed with T-leaves needed much more leaf material to end up with the same weight of pupae than the larvae fed with S-leaves. VOCs: In an extensive experiment the volatile substances emitted by T and S-oaks during feeding of leaf of T. viridana were measured online. We found clear differences in the amount of e.g. sesquiterpenes emitted by S- and T-oaks. Furthermore the S-oaks seem to emit attractants which leads to a higher amount of larvae feeding on them.

Conclusions: We started the project with an observation, thus, we first identified phenotypes. Now, concerning the behavioural and biochemical results, we conclude that there are other factors than only environmental ones which lead to tolerant and susceptible oaks. There are physiological differences between S- and T-oaks and the identification of the candidate genes responsible for these differences is ongoing. This approach will give us an insight into the functional genomics of Q. robur relating to the feeding of herbivorous insects. The question still remains unsolved whether the Tortrix-oak interaction is highly specific, or basics of the "Tortrix tolerance" can be transferred to other host-pathogen interactions. With the identification of molecular and biochemical markers of "Tortrix tolerance" in oaks we can contribute to decision support in sustainable forest management.

P102 Low temperature stress and changes in the lignin content and composition in Eucalyptus globulus

BMC Proceedings 2011, 5(suppl 7)p102

It is known that many abiotic stresses, such as mineral deficiency, drought, UV-B radiation, wind and low temperatures, alter the quantity and composition of lignin in several species [1]. The aim of this work was to verify if the cold stress may cause changes in the quantity and composition of lignin in E. globulus. Additionally, we analyzed whether these changes can also be beneficial from the industrial point of view, that is, if this would allow a better extractability of lignin in this species, which is a desirable feature in the manufacture of paper. During the day, all plants were kept in a greenhouse at room temperature but at night, half of plants was transferred to growth chamber at 12 °C and half to 25 °C. These conditions were kept during 20 days. The stems of plants from the two groups were collected and analyzed for total lignin with thioglycolic acid [2] and submitted to thiocaclylization and GC-MS analysis for the determination of the monomeric lignin composition [3]. Part of the material was used to determine the digestibility of cellulose [4]. It was observed that cold reduced the accumulation of lignin in E. globulus. GC-MS analysis showed that the proportion of the S/G was reduced in plants subjected to low temperatures and it was also observed a lower digestibility of cellulose in these plants, indicating that this lignin could be more difficult to be removed in industrial processes of papermaking.

These results have been related with gene expression studies for the enzymes of the lignin biosynthesis pathway and may contribute to understand the processes controlling lignin deposition in eucalyptus.

P103 Drought stress and changes in the lignin content and composition in Eucalyptus
Julliana Moura-Sobczak, UIara Souza1, Paulo Mazzafera1
1. Departamento de Fisiologia Vegetal. Instituto de Biologia - Unicamp. CEP: 13083-970 Campinas, SP, Brazil
E-mail: uiaraks@yahoo.com.br
BMC Proceedings 2011, 5(suppl 7)p103

It is known that many abiotic stresses, such as mineral deficiency, drought, UV-B radiation, wind and low temperatures, alter the quality and composition of lignin in several species [1]. The aim of this work was to verify if the drought stress may cause changes in the quantity and composition of lignin in Eucalyptus globulus Labill and in the hybrids E. urograndis (E. urophylla x E. grandis) and E. urophylla (E. globulus x E. urophylla). In the experiment the plants were divided in three groups (control, drought and drought recovered). The control plants were irrigated daily. The plants from the group “drought” were not irrigated and were collected when wilt symptom was observed. The plants from the group “drought recovered” were irrigated when wilt was observed and were collected after recovery.

Samples of basal and apical regions of the stem were collected and analyzed for total lignin with thioglycolic acid [2] and analyzed by GC-MS to determine lignin monomeric composition [3]. E. urophylla subjected to drought decreased the amount of lignin in the stem apical regions and increased lignin in the basal region. E. globulus showed opposite behavior in apical regions and showed no significant changes in the basal regions. E. urophylla showed a pattern similar to E. urophylla in apical regions and similar to E. globulus in basal regions. Although E. urophylla and E. urophylla reduced lignin and E. globulus increased in the apical part of the stem, it was observed that these different adjustments of lignin deposition eventually result in an increased proportion of S/G in both species. Moreover, when the amount of lignin is increased in the basal regions of E. urophylla there is a decrease in the proportion S/G. Increasing the proportion S/G, either by increasing the amount of lignin-rich syringyl units or reduction of coniferyl units can be an important aspect in the adaptation of both species to drought stress.

E-mail: Jonathan.Botha@fabi.up.ac.za

BMC Proceedings 2011, 5(Suppl 7):P104

The conversion of biomass to biofuels requires heat, pressure and acid treatments to overcome the recalcitrance of the cell wall and remove lignin that hinders access to cellulose. Economic production of biofuels from lignocellulosic biomass and efficient sugar release depends on the ability to reverse and overcome this natural recalcitrance of the plant cell wall.

Most of the current ideas and methods to generate lignocellulose feedstock which is more amenable to saccharification, are limited to the modification or down-regulation of the lignin biosynthesis. This often results in dwarfing, xylem vessel collapse or reduced fitness to stress. In order to overcome these limitations, we present here a novel approach for cell wall remodeling. By introducing new trans-genes from algae, fungi and viruses we create “Trojan Horses”: polymer pockets of enhanced solubility within the cell wall, thus increasing cellulose accessibility to solvents and enzymes. Two different methodologies are presented. The first includes transgenic introduction of soluble polysaccharides such as hyaluronan into the cell wall during its development, leading to its intercalation with the cellulose microfibrils. Upon processing, these soluble intercalated polysaccharides are washed away, resulting in highly porous cell walls with increased accessibility to hydrolytic enzymes. The second methodology involves modification of the cellulose by expression of recombinant cellulobiose dehydrogenase (CDH) in plant cell walls, leading to disruption of the cellulose microcrystalline lattice and thus increasing hydrolytic enzymes accessibility. Both methodologies result in transgenic plants that exhibit significantly enhanced cellulose hydrolysis, while maintaining their physiological and structural integrity. This novel concept provides new prospects for more economical production of liquid biofuel to substitute fossil fuels.

BMC Proceedings 2011, 5(Suppl 7):P105

Background: NAC and MYB transcription factors (TFs) have been shown to play prominent roles in the regulation of plant developmental processes. Two Arabidopsis thaliana NAC domain TFs (AtSND2, AtSND3) and one MYB domain TF (AtMYB103) were shown to be downstream targets of two master regulators of xylem fibre cell development, NST1 and SND1 [1,2]. These TFs were able to induce the expression of a GUS reporter gene under the control of the AtCesA8 promoter [3], indicating that they may be involved in the regulation of cellulose biosynthesis in the secondary cell walls of A. thaliana xylem fibres. It is hypothesized that putative orthologs of these TFs will also play important roles in regulating fibre secondary cell wall biosynthesis in woody plants such as Eucalyptus grandis. The transcriptional network regulating wood fibre development is uncharacterized in E. grandis, therefore it would be beneficial to identify upstream components of this transcriptional network in E. grandis. In this ongoing study we aim to identify TFs which bind to the promoter of the putative ortholog of AtSND2 in E. grandis (EgSND2) and possibly also to the promoters of the orthologs of AtSND3 and AtMYB103. In parallel, we are characterizing the detailed heterologous expression patterns of the EgSND2, EgSND3 and EgMYB103 promoter regions in A. thaliana plants. This work forms part of an effort to elucidate the transcriptional network regulating wood fibre development in E. grandis.

Methods: A reverse BLAST approach was used to identify candidate orthologs of AtSND2, AtSND3 and AtMYB103 in Eucalyptus, Populus and Vitis. A dicistron cis-element analysis was performed on the promoter regions of the putative orthologs to identify previously characterized and novel cis-elements. The 1.5 kb regions upstream of the translational start site (TSS) of EgSND2, EgSND3 and EgMYB103 were isolated from E. grandis genomic DNA. The amplified fragments were cloned into pMD18T, a GUS reporter vector, and introduced into A. thaliana Col-O plants for heterologous GUS expression analysis. The same reporter constructs were also transformed directly into the vascular cambium of potted E. grandis plants to determine endogenous promoter activity by introduced Somatic Sector Analysis (ISSA, [4]). Qualitative GUS reporter analyses were performed on the EgSND2promoter::GUS, EgSND3 promoter::GUS and EgMYB103 promoter::GUS constructs in Arabidopsis plants at 1, 3 and 6 weeks. A 500 bp truncation upstream of the TSS of EgSND2 was generated and cloned into the phIS2.1 vector along with the 1.5 kb EgSND2 promoter sequence for use in yeast one-hybrid (Y1-H) screening. Candidate proteins which bind to the cloned promoter sequences will be identified using Y1-H analysis and further characterised.

Results and discussion: A number of previously described (e.g. [5]) and novel cis-elements were present in the three cloned Eucalyptus promoters (EgSND2, EgSND3 and EgMYB103) suggesting regulation by an overlapping set of upstream transcription factors. The 1, 3 and 6-week GUS analyses of the EgSND2 promoter::GUS and EgSND3 promoter::GUS constructs revealed strong GUS expression in vascular tissues, but the GUS expression was not specific to vascular tissues as reported for the endogenous AtSND2 and AtSND3 genes [3]. This suggests that the 1.5 kb region upstream of the translational start site may not be sufficient for fibre-specific expression in a heterologous system. Similarly, the EgMYB103 promoter::GUS construct was expressed in stems and leaves, in contrast to strong stem specificity reported by Zhong et al. [3] for the Arabidopsis ortholog. ISSA (ongoing) results of endogenous expression in E. grandis may clarify the possible regulatory divergence in these promoter sequences. We hope to soon identify and functionally annotate a number of protein candidates binding to the EgSND2 promoter using Y1-H analysis.

Conclusions: The EgSND2, EgSND3 and EgMYB103 promoters were found to contain common cis-regulatory elements, which suggests at least partial co-regulation in E. grandis. The 1.5 kb upstream regions of EgSND2, EgSND3 and EgMYB103 induced strong heterologous GUS expression in vascular and non-vascular tissues of A. thaliana suggesting either that these promoter sequences have functionally diverged in Arabidopsis and Eucalyptus, or that the 1.5 kb upstream regions alone are not sufficient to induce fibre-specific expression as previously reported in Arabidopsis.

BMC Proceedings 2011, 5(Suppl 7):P106

Background: Eucalyptus species are the most widely planted hardwood trees in the world representing more than 4.75 million ha in Brazil. Their high productivity, valuable wood properties and wide adaptability could allow sustainable and cost-efficient production of lignocellulosic bioenergy. The main limitation to this objective is wood recalcitrance to degradation which is linked to the structure and composition of lignified secondary cell walls. Lignin, for example, impairs the accessibility of cellulose during kraft pulping as well as during saccharification, a key step of bioethanol production.

The application of nitrogen fertilizers is one strategy to increase growth rates and productivity since nitrogen is one of the most limiting nutrient for tree growth and carbon sequestration. However, the effects of nitrogen availability on wood properties and related gene expression are poorly understood.

In poplar, it was recently reported that N fertilization increased aerial biomass, while in wood, fibre morphology and secondary cell wall structure and composition were modified. An increase in cellulose coupled with a decrease in lignin was observed and the mRNAs profiles evaluated by microarray showed that nitrogen and tension wood have overlapping effects [1]. Moreover, a highly significant genetic correlation was observed between plant growth and lignin/cellulose composition. Quantitative trait loci co-localization identified the genomic position of potential pleiotropic regulators [2].

In order to get an insight on the regulation of nitrogen availability on wood formation in Eucalyptus, we have studied the effects of nitrogen fertilization on xylem transcriptome profiles using RNA-seq technology.

Methods: An experimental system was set up in which rooted cuttings of Eucalyptus urophylla x grandis were fertilized during 30 days with three different amounts of N (limiting, -N; adequate, CT; excess, +N). For the treatment with excess of N fertilization, we used two different nutrient solutions with different concentration of NO3 and NH4.

Histochemical analyses were performed on stem transverse sections (80 µm thick) obtained using a Vibratome (LEICA VT 1000s). The Weisner reagent (phloroglucinol-HCl) was used in order to detect lignified cell walls, and calcofluor reagent to evaluate the cellulose content by fluorescence. The samples were observed in confocal microscopy (SP2-AOBS, Leica) and under bright-field microscopy (DM IRBE, Leica) coupled with a CCD camera (DFC 300 FX, Leica).

The construction of the RNA-seq libraries and sequencing were performed according to Illumina’s protocols. Prior to analyze the RNA-seq data, we have assembled the Eucalyptus ESTs from GENOLYPTUS and NCBI. The 53,412 unigenes produced were automatically annotated using BLAST (e-value cutoff of 1e-5) against different sequence databases. The RNA-seq reads were aligned against the assembled unigenes using the SOAP2 aligner [3] configured to allow up two mismatches, discard sequences with ‘N’s and return all optimal alignments. In order to perform the differential expression analysis between libraries, a normalization and statistics pipeline were applied using DEG-seq software [4] considering 99% of confidence rate (cut-off value of 0.01).

Results and discussion: The intensity of staining with phloroglucinol was higher in stem sections from samples grown under -N treatment as compared to control, whereas it was lower in both +N treatments. This suggests that lignin biosynthesis is decreased in presence of excess of nitrogen fertilizer. We could also observe in the +N samples, an increase in cellulose staining intensity with the calcofluor reagent specially noticeable when comparing with -N samples suggesting that nitrogen also influence cellulose biosynthesis.

The RNA-seq analysis generated 123,121,154 sequence reads after filtering. Of the total reads, about 86 millions matched either to a unique (47.9%) or to multiple (21.8%) EST locations. Each nitrogen treatment was represented by at least 28.8 million reads, a tag density sufficient for quantitative analysis of gene expression.

The sequence reads were aligned on the new Eucalyptus EST assembly resulting in 36,125 unigenes expressed (15,293 contigs and 20,832 singlets). After statistics analysis, we determined 14,400 differentially expressed genes, that for a preliminary analysis were divided in two scenarios: the genes down-regulated in -N and up-regulated in both +N treatments (8,967 genes), and the genes up-regulated in -N and down-regulated in both +N treatments (5,433 genes).

To facilitate the global analysis for each scenario, gene ontology (GO) classification (http://www.geneontology.org) was performed and showed differences in some biological process categories. For instance, we observed that genes involved in the biosynthesis of cell wall main components (lignin, cellulose and hemicelluloses) were differentially expressed between the treatments. For example, some genes of the lignin biosynthetic pathway were up-regulated in the treatment with less nitrogen (-N) and down-regulated in both +N treatments.

Conclusions: This first analysis in Eucalyptus allowed us to show an effect of nitrogen fertilization on cell wall composition both at the histological and at the gene expression level. We believe that further experiments completed by chemical analysis of wood samples will give a better insight of the mechanisms involved in nitrogen effects on wood formation. This knowledge will be important to address new demands on better suited biomass quality for industrial applications.

Background: Cellulose is an important biopolymer produced by all plants and is used in a number of different industries, including for pulp and paper production. Cellulose is deposited into the plant cell wall by a large membrane-bound protein complex, which is composed of different cellulose synthase (CESA) proteins. The cellulose content and pattern of deposition in plant cell walls is highly variable depending on the function of the cell. All plant cells have a thin primary cell wall, but a number of plant cell types, including xylem cells, also deposit a secondary cell wall to give these tissues mechanical strength required to perform their function. Different cellulose synthase (CesA) genes have been shown to be involved in the deposition of primary and secondary walls. In Arabidopsis, three CesA (AtCesA4, 7 and 8) genes have consistently been associated with cells depositing secondary cell walls, while a different set of CesA genes have been shown to function during primary cell wall formation [Reviewed in 1]. These findings have been mirrored by studies of CesA gene orthologs in...
Populus and Eucalyptus[2-4]. While there have been a number of studies on CesA genes and their functions, much less is known about the regulation of these genes. In a previous study, we investigated the promoters of CesA genes involved in primary and secondary cell wall formation by performing a phylogenetic footprinting analysis to identify cis-elements conserved in the promoters from orthologous Arabidopsis, Populus and Eucalyptus cellulose synthase genes [5]. We identified a number of putative cis-regulatory elements that may play a role in the regulation of cellulose biosynthesis during primary and secondary cell wall formation. In the current study our aim is to further validate the cis-elements identified in the CesA gene promoters by investigating their conservation across different Eucalyptus species and to determine the regulatory function of these promoter regions and the proteins which bind to them.

Methods: A number of different methods are being employed to investigate the regulatory functions associated with the EucalyptusCesA promoters. Firstly, to validate the cis-elements previously identified, we cloned and sequenced the promoters of six CesA genes from 13 different Eucalyptus species. The promoter sequences were analysed on the nucleotide diversity level. The cis-elements identified in the current study were mapped onto the cloned promoter sequences and analysed for conservation in sequence and position. Next, we studied the possible roles of promoter regions harbouring conserved cis-elements in spatio-temporal regulation of CesA genes. We tested regions upstream of the EucalyptusCesA1 (EgCesA1) promoter for involvement in spatio-temporal regulation by cloning the full-length (2 kb) promoter and a series of truncates thereof upstream of the β-glucuronidase (GUS) reporter gene. These constructs were used to transform Arabidopsis (floral dipping) and Eucalyptus (induced Somatic Sector Analysis, [6]). The GUS expression patterns were compared to the pattern produced by the 2 kb EgCesA1 promoter. Finally, promoter regions identified as functionally active and harbouring conserved elements of interest are being used to screen a Eucalyptus immature xylem cDNA expression library for yeast-1-hybrid interactions to identify proteins which interact with these regions.

Results and discussion: Studying the diversity of CesA promoter sequences and cis-elements in 13 Eucalyptus species provided us with valuable insight into the relative conservation of specific promoters regions and the cis-elements within these regions. We found that the overall nucleotide diversity of the promoter sets varied greatly from promoter to promoter, but we could identify regions in the promoters that were as conserved as coding regions. We found that in many cases these localized decreases in nucleotide diversity corresponded to clusters of conserved cis-elements which were identified previously [5]. This was particularly noticeable at the transcriptional start site for most genes and in this region we noticed a repeat element in all of the promoters investigated. Some elements were also shown to be specific to either the primary or secondary cell wall associated promoters. The cis-element information obtained from this study was used to create seven truncates of the EgCesA1 promoter. Using GUS expression analysis in Arabidopsis we identified a number of repression and activation sites within the promoter. We also observed a loss of leaf (vein) expression 800 bp upstream. One of the repeat elements fused to the 5′UTR greatly enhanced overall GUS expression in a non-specific way. In a Eucalyptus background (ISSA), six of the seven truncates showed xylem-specific expression, but the 5′UTR and repeat elements showed GUS expression in phloem and xylem. These regions have been used to construct bait vectors for Yeast-1-hybrid screening which is still ongoing.

Conclusion: In this study we addressed three main objectives, (1) investigate the evolution of the EucalyptusCesA promoters and cis-elements associated with primary and secondary cell wall formation, (2) investigate the expression patterns of truncated versions of the EgCesA1 promoter using the GUS reporter system and (3) test the EgCesA1 promoter regions affecting gene expression in a yeast-1-hybrid assay to identify possible regulators of this gene. We have identified regions in the promoters that were conserved and corresponded to previously identified cis-elements. Using this information we produced seven promoters that showed conserved transcriptional and cis-elements in the EgCesA1 promoter which affect GUS expression patterns. These results will aid in understanding and elucidating transcriptional networks regulating xylogenesis in woody genera such as Eucalyptus.

rapidly to environmental stresses such as changes in temperature and salinity, heavy metals and water deficit. Efficient stress response systems are prerequisites for plant survival and productivity [1]. Molecular chaperones (or Heat Shock Proteins – HSP) compose a ubiquitous class of proteins involved in cellular protein quality control (PQC) and homeostasis. They play a critical role in folding and degradation of polypeptides, and therefore, in maintenance and modulation of cellular pathways, which are dependent of function (correct folding) and availability (stability and degradation) of involved proteins, under normal and stress conditions [2]. Genetics and proteomics studies of wood formation have highlighted some chaperones up-regulated in xylem of Eucalyptus, Pinus and Populus species, stating that they may play an important role in cell wall formation and xylem development [3,4].

Figure 1 (abstract P109) Molecular chaperones up-regulated in E. globulus xylem in comparison to E.grandis xylem.

Figure 2 (abstract P109) Molecular chaperones, co-chaperones and Heat shock transcription factors are up-regulated in E. urograndis narigenin-chalcone (black bars) and naringenin-supplemented (gray bars) in comparison to control group.
Different species of Eucalyptus are known for their superior performance in growth, wood quality and resistance to different types of stress [5]. Such characteristics are probably driven by distinct gene expression coordination in xylogenesis. Eucalyptus grandis is one of the most planted species in the world due to its rapid growth, wide adaptability and wood quality. Eucalyptus globulus wood has higher S/G ratio which provides high yields in cellulose extraction [6].

Lignin extraction consumes large quantities of chemicals and energy, and many efforts have been made to improve this process by modifying lignin content or composition in trees, in order to reduce lignin content or make it easier to extract. Results have been achieved by supplementation and genetic modification [7,8]. This study aims to identify chaperones possibly involved in wood formation and quality of wood for pulp and paper industries.

Methods: The RNA-Seq reads were produced from two xylem libraries for comparison between species (Eucalyptus globulus and E. grandis), and from two libraries for evaluating flavonoids supplementation (E. urograndis supplemented with naringin and naringin-chalcone).

Reads were aligned against the assembled unigenes using SOAP2 aligner [9] configured to allow up two mismatches, discard sequences with “N”s and return all optimal alignments. To perform the differential expression analysis between libraries, a normalization and a statistical pipeline were applied using DESeq software [10] (confidence rate: 99%; cut-off: 0.01). RNA-seq libraries and Gbrowse are available at http://bioinfo03.ibi.unicamp.br/eucalyptus/.

Results and discussion: In this study, we identified chaperones differentially expressed between Eucalyptus species. RNA-seq analysis revealed chaperones as smHsp, Hsp40, Hsp70, Hsp90 and Hsp100 between 1 and 3 fold up-regulated in xylem of E. globulus (Figure 1). Eucalyptus urograndis naringenin-chalcone or naringenin supplemented also presented molecular chaperones highly expressed (Figure 2). Recent findings reported that supplementation with these flavonoids can inhibit lignin biosynthesis, and change lignin content and composition [10].

SmHsp family is active in a wide range of environmental stresses, including heat, cold, drought, salinity and oxidative stress [11]. Gion et al [4] noted smHsp accumulation in wood forming tissues, and suggested a role in extending the cell wall thickening phase during xylogenesis.

Hsp70 family acts in protein refolding, translocation, and facilitating the degradation of unstable proteins, directing them to lysosomes or proteasomes [12].

Hsp90 family has a select group of substrate proteins as polymersases and kinases [13]. Ina. thaliana some kinases are required for optimal cell elongation, which is important for plant growth and vascular system formation [14].

We have successfully identified chaperones with higher expression on E. globulus xylem and in E. urograndis flavonoids-supplemented plants, which provide evidences to link xylogenesis and chaperone expression. Those findings are crucial on helping to elucidate the role of chaperones on plant development, stress response and wood formation.

identification of their direct targets genes and of their protein partners. We have constructed a yeast-two-hybrid library from Eucalyptus xylem that will also be instrumental for deciphering the interactants of landmark genes for the International Eucalyptus community. Thanks to the recent release of the E. grandis genome (Eucalyptus grandis Genome Project 2010, http://www.phytozome.net/eucalyptus), we have performed a genome-wide survey of the large R2R3-MYB superfamily. The phylogenetic comparison of this family with Arabidopsis, rice, poplar and grapevine showed a marked expansion of some clusters putatively involved in wood-related processes. Some R2R3 MYB genes seem to be specific of woody plants. The spatial-temporal expression patterns of members of several subgroups are currently being studied. Although Auxin is known as a key regulator of cambium activity and wood formation, the Auxin response mediators [Auxin/Indole-3-Acetic Acid (Aux/IAA) and Auxin Response Factor (ARF) transcription factors] extensively characterized in model plants, are still largely uncharacterized in tree species. We have identified 23 Aux/IAA and 17 ARF in the E. grandis genome. Comparative phylogenetic analysis revealed that several Aux/IAA and ARF subgroups have differentially expanded or contracted amongst the three dicotyledonous plants studied (Arabidopsis, Populus and Eucalyptus). Expression analysis and EST database surveys are currently underway to explore the transcript levels of each member in the different organs and tissues of Eucalyptus at key developmental stages as well as in response to hormonal treatments and to environmental stresses. Further functional genomics studies conducted on new candidate transcription factors, their regulation under the developmental or environmental stimuli will help identifying major factors underpinning the physiochemical properties of cell walls, the recalitrance of which remains a key scientific challenge for establishing highly efficient, sustainably produced, second-generation biofuels.

Sucrose export from source organs and its subsequent distribution among differentiating organs in woody tissues is essential for normal growth. Light, hormones and sugars transporters (SUTs) are essential for normal growth. To find innovative solutions for the use of lignocellulosic wastes, the aim of this study was to evaluate the ability of converting cellulose bleached pulp into reducing sugars from enzymatic hydrolysis, at different exposure times.

**Methods:** Cellulose pulp samples were weighed in the amount of 0.2 g and transferred to Falcon tubes, in which were added 40 mL of 50 mM sodium citrate buffer with pH 4.8. For hydrolysis, 0.05 mL of cellulase (Celluclast 1.5 L) and 0.05 mL of cellobiase (Novozyme 188) enzymes were transferred to each tube. The Falcon tubes were incubated in shaker at 50±1 °C and 250 rpm for 24, 48, and 72 hours. Subsequently, reducing sugars were quantified through the dinitrosalicylic acid (DNS) method [2].

**Results and conclusions:** The results were very similar for all incubation times. The average reducing sugar concentrations were 4.15 g/L, 4.14 g/L and 4.16 g/L, for 24, 48, and 72 hours, respectively. These results show that the hydrolysis incubation time higher than 24 hours does not improve the conversion of cellulose into glucose. One possible explanation would be the fact that the enzymes mainly hydrolyze amorphous or less ordered crystalline cellulose. Therefore, remains just highly crystalline cellulose molecules, hindering the access of the enzyme. In other words, this highly crystalline cellulose prevents the total conversion, even over long periods of time. X-ray diffraction (XDR) measurements will be done to check this hypothesis.

Energy Poplar (Enhancing Poplar Traits for Energy Applications) is an EC Seventh Framework Programme project aimed at further improving poplar trees as an energy crop. The work is directed to understand and improve traits such as yield and wood properties coupled to Bioethanol production. The project also addresses environmental and economical sustainability questions. The final goal of ENERGYPOPLAR is to develop poplar as a bioenergy short rotation coppice crop, suitable for large-scale deployment in Europe in areas unlikely to be used for food agricultural production. All will be placed in an environmental framework to ensure environmental sustainability with respect to land use, inputs and soil status. World primary energy consumption increased by 2.4% in 2007. With the worlds growing energy consumption, the development and use of renewable, sustainable liquid bio fuels has become a strategic priority for
the EU. Bio fuels can minimize energy import dependence, reduce greenhouse gas emissions and assist rural and agricultural development. Bio ethanol can be produced from energy crops that do not compete with food crops for land use and can be directly used by current transportation vehicles. This alcohol can be produced from biomass feedstock and in particular from cellulose, a sugar based polymer present in the cell wall of plants. Such crops are known as ‘second generation’ bio fuel crops. To develop a new bio ethanol industry competitive with fossil fuels, the quality of the biomass feedstock, the methods to produce ethanol from cellulose and the yield per hectare must be improved. Energy trees must also support environmentally sustainable agriculture that uses less agrochemicals, develops rural economies and spares natural forests from agricultural expansion.

Poplar is an economically and ecologically attractive energy crop because it displays a wide range of growth habits and can grow on marginal lands unsuited for food crops with reduced input costs and optimized land management. Additionally, poplar is a commercial crop and the model organism for hardwood tree genomics and physiology. http://WWW.Energypoplar.eu for more information.

**BMC Proceedings** 2011, 5(Suppl 7):P114

**Background:** Transcription factors (TFs) play important roles in the regulation of secondary cell wall (SCW) biosynthesis in herbaceous and woody plants. In Arabidopsis, the onset of SCW deposition is initiated by a nexus of NAC, MYB, homeodomain and several other families of TFs, which function in a transcriptional network regulating SCW biosynthetic genes. NAC family members SND1/NS1 and VND6/VND7 have been identified as functionally redundant master regulators of SCW formation in fibres and vessels, respectively [1,2]. Arabidopsis plants overexpressing SND2, an indirect target of fibre master regulator SND1, exhibited increased SCW thickness in internode stem fibres, whilst dominant repression lines exhibited a decrease in SCW fibre thickness associated with a reduction in glucose and xylose cell wall sugar content [3]. The ability of SND2 to transactivate the CesA8 promoter [3] suggested that SND2 may regulate cellulose biosynthetic genes during fibre SCW formation. The evaluation of this hypothesis necessitates the identification of all downstream genes potentially regulated by SND2, and the analysis of SCW chemistry and morphology in overexpression lines. The aims of this ongoing study is to further elucidate the role of SND2 in fibre SCW formation through microarray analysis of overexpression lines and by independent confirmation of the effect of SND2 overexpression on fibre SCW chemistry and morphology in Arabidopsis plants.

**Methods:** We generated 2x3SS:SN2 Arabidopsis thaliana Col-0 plants, screened them for CesA8 upregulation and phenotypically assessed several homozygous (T4) transgenic lines. Internode stem fibre SCW thickness was measured from light and scanning electron micrographs, and the cell wall monosaccharide and Kason lignin composition of stems was determined relative to the wild type. We performed microarray analysis of the inflorescence stem transcriptomes of wild type and several homozygous (T4) transgenic lines. We performed microarray analysis of the inflorescence stem transcriptomes of wild type and several homozygous (T4) transgenic lines. The sum of the expression levels of three CesA1, CesA2 and CesA3 to 4CL showed positive correlation with a ratio of HC/KL content that positively correlated between gene expression levels and wood qualities such as KL and 4CL in the absence of other factors. We investigated correlation between relative expression levels of these genes and wood qualities.

**Results:** Transgenic Arabidopsis (T4) lines showed no significant external phenotype, and we were unable to reproduce the increased fibre SCW thickness phenotype reported by Zhong et al.[3]. We identified a single homozygous line with CesA8 upregulation and moderate SND2 overexpression. Whole-transcriptome analysis of the line revealed the upregulation of several TFs and genes associated with SCW biosynthesis, which were reproducibly upregulated in an independent trial. We additionally observed possible ectopic artifacts and gene dosage effects associated with excessive constitutive expression of the SND2 gene. Chemical analysis revealed only minor changes in SCW monosaccharides, despite the upregulation of SCW biosynthetic genes.

**Conclusions:** Our results implicate SND2 in the regulation of cellulose and non-cellulosic components of fibre cell walls, and we provide a model for the position of SND2 in the transcriptional network regulating fibre SCW formation.

**BMC Proceedings** 2011, 5(Suppl 7):P115

Eucalyptus species constitute the most widely planted hardwood trees in temperate and subtropical regions. Their wood is used as a raw material for the production of cellulose. Eucalyptus species have fast growth rates and the ability to adapt to a broad range of geographic locations. Most importantly, Eucalyptus has been listed as one of the candidate biomass energy crops [1]. Eucalyptus globulus is the main hardwood species grown in pulpwood plantations in temperate regions of the world. In this study, we focused on four kinds of key genes, 4-cumarate-CoA ligase (4CL), LIM domain transcription factor (LIM) [2], coniferaldehyde 5-hydroxylase (CAlSDH) and the three catalytic units of cellulose synthase (Cesa1, CesA2 and CesA3) influencing wood quality. We investigated correlation between relative expression levels of these genes and wood qualities.

We have cloned the genes encoding LIM, 4CL, CAldSH and the cellulose synthase (Cesa1, CesA2 and CesA3) from E. globulus by the method of cDNA library screening (Fig.1). A cDNA library was constructed using mRNA purified from stems of four-month old E. globulus grown in the greenhouse. The expression levels of LIM in basal stems of ten independent E. globulus lines showed similar patterns to those of 4CL, indicating that the LIM may control 4CL expression. We investigated the correlation between gene expression levels and wood qualities such as Kason lignin (KL) content, syringyl/guaiacyl (S/G) ratio and holocellulose (HC) content. Expression of the LIM and 4CL were positively correlated with KL content. A highly significant positive correlation was observed between CAldSH expression and S/G ratio. Furthermore, a ratio of the sum of the expression levels of three Cesa1, CesA2 and CesA3 to 4CL showed positive correlation with a ratio of HC/KL content that positively correlated to the chemically extracted fiber content in this woody plant. Overall, our results provide a strong foundation for manipulating candidate genes such as LIM, 4CL, CAldSH and CesA towards the production of desirable wood qualities in an extremely important biomass plant, the Eucalyptus species.

Pre-treatment of eucalypts biomass towards enzymatic saccharification

Washington Luiz Magalhães¹, Cristiane Helm¹, Patricia Silva¹, Edison Lima¹, Kleber Hoffman², Amanda Higa², Tielidy Lima²
¹Embrapa Forestry, Brazil; ²UFPR, Brazil
E-mail: wmagalha@cpnf.embrapa.br

Background: There are a few possible ways to produce ethanol from lignocellulosic biomass, for instance, thermochemical and acid hydrolysis. However, enzymatic hydrolysis of carbohydrates is considered the greenest process for saccharification, followed by sugar fermentation into ethanol.

The main challenge of the enzymatic saccharification process is that cellulose is not exposed to the enzyme action in the lignin matrix. The cellulose molecules are arranged in semi-crystalline nanofibrils immersed in lignin matrix with hemicelluloses (polyoses) and extractives between them acting as coupling agents. These nanofibrils are placed together to form helical microfibrils inside the cell wall. Thus, a pre-treatment is necessary to make room for the enzymes to reach the cellulose fibril surfaces in order for the whole process to become economically feasible. There are many pre-treatments proposed in specialized literature, but their efficiencies are dependent on the biomass composition [1-4]. Moreover, these treatments have to address some constraints such as the recyclability of the chemicals used, low consumption of energy, and sustainability concerns.

We devised a future possibility of a cellulose pulp mill to be transformed into a biorefinery, where besides cellulose pulp, ethanol could also be produced. In the Brazilian pulp mill industry, the process most commonly produced is the Kraft process, so the digestion with green liquor can be adapted for pre-treatment towards enzymatic saccharification. Also, the industry had already tackled recycling of the black liquor – obtained after wood chips digestion –, recovering thermal energy by burning lignin and recovering the green liquor. This work is part of our research to evaluate some modifications on the green liquor digestion towards enzymatic saccharification. We evaluated efficiencies of some pre-treatments with green liquor through enzymatic hydrolysis for holocellulose saccharification.

Methods: A wood log from a 7-year old tree of Eucalyptus benthamii was cut into discs. They were cut into 30° wedges and were then ground using a Willey mill and sifted to be between 20 and 40 Tyler mesh. Composition of the E. benthamii wood obtained by NMR standards was: 3% of total extractives; 28.4% of Klasson lignin; 0.03% of ash and 3.5% of syringyl:guaiacyl molar ratio.

Table 1 shows the characterization of the green liquor acquired from Iguaçu Celulose Papel S.A.

The pre-treatment conditions used in this study were two levels of temperature – 120 and 180 °C – and three levels of reaction time – 1, 2, and 3 hours. Cylindrical stainless steel reactors (Parr, USA) with volume capacity of 50 mL were used. The reactors were heated in an aluminum dry block furnace (Marconi, Brazil) with a temperature and time controller. The ratio of solid wood and green liquor was 1:4 (g.mL⁻¹). Typical values were 4 g of dry biomass in 16 mL of green liquor per reactor.

The pre-treated biomass was digested using Falcon tubes with enzymes in a buffer solution of sodium citrate (pH of 5.0) in an incubator (Tecnal TE-420, Brazil) at 50 °C and 250 rpm during 24 hours. The enzymes used were cellobiase from Aspergillus niger (Novozyme 188) and cellulase from Trichoderma reesi (ATCC 26921), acquired from Sigma Aldrich, USA. Typically, the proportion was 0.2 g of dry biomass, 40 ml of buffer solution, 46 mL of cellobiase and 90 mL of cellulase (both used as received). After saccharification, the hydrolyzate was filtered and the reducing sugars were quantified through the dinitrosalicylic acid (DNS) method.

Results: Table 2 shows the solid mass loss after treatment, the total reducing sugar released after enzymatic hydrolysis, and the global yield of saccharification.

As can readily be seen on Table 2, temperature plays a crucial role in exposing cellulose for enzymatic hydrolysis, as does the length of cooking. For lowest temperatures, (120 °C) increasing time causes increased sugar release and conversion yield. On the other hand, for the highest temperature level (180 °C), the time of cooking plays a more complex role. The treatment at 180 °C after 1 hour reaches the highest sugar conversion based on holocellulose content of untreated biomass. The above results can be explained by the following suppositions. Increasing treatment time to 2 and 3 hours results in hemicellulose and amorphous cellulose losses, which decreased conversions yield. However,

when the treatment time was increased to 3 hours, besides amorphous holocellulose loss, there was also the occurrence of crystalline modification of part of the crystalline cellulose type I into amorphous and cellulose type II. Both amorphous and crystalline type II cellulose are enzymatic digested easier than crystalline type I cellulose. This could explain why sugar conversion yield after 2 hours of treatment at 180 °C are smaller than after 3 hours. XRD and chemical characterizations of the pre-treated biomass have to be done in order to corroborate with the above suppositions.

Conclusion: Simple modifications of the Kraft process can be considered as an alternative route for pre-treatment of woody biomass towards enzymatic saccharification.

BMC Proceedings 2011, 5(Suppl 7):P117

Background: Researches concerning renewable energy sources and wastes recycling are strategic to ensure energetic and environmental sustainability of the planet. In this scenario, biofuels (including bioethanol) have attracted increasing attention. Most ethanol is currently produced from sugar- and starch-based feedstocks, such as sugar cane in Brazil and corn in the U.S.A. However, lignocellulosic biomass also presents great potential for being used as an alternative raw material. Unlike ordinary feedstocks, sugars from cellulotic biomass are not readily available for fermentation and conversion to ethanol. A preliminary pretreatment step is necessary in order to remove the lignin that involves the cellulose and hemicellulose, acting as a barrier. In the following step, fermentable sugars can be released by enzymatic hydrolysis of polysaccharides. Finally, monosaccharides can be converted into ethanol by anaerobic fermentation [1,2].

This process allows the use of forest wastes to produce ethanol. Besides adding value to these byproducts, this action could contribute to reducing environmental problems related to waste disposal. Several solid byproducts from pulp and paper industry have a high conversion potential into ethanol [3-7], since they have high carbohydrate content and susceptibility to hydrolysis process. This is due to the fact they have already undergone a previous treatment of the fibers. One example is the sludge generated in wastewater treatment of paper recycling industries, which is composed primarily of cellulose and ash. Although studies have been conducted focusing recycling and reusing, currently its primary destination has been the disposal in landfills, causing high costs and requiring large storage areas. As product, although high content of cellulose, the production of wet sludge can reach one ton per ton of paper produced [8]. Therefore, suitable utilization of such waste would result in significant economic benefits to the pulp and paper sector.

The aim of this study was to evaluate the enzymatic digestibility of byproducts generated by paper industry, including samples of recycled paper sludge and bleached and unbleached pulps.

Methods: The "recycled paper sludge" was a pressed solid material resulting from the wastewater treatment process of a paper recycling mill. Two samples obtained from Kraft pulping process were also used: an unbleached pulp and a bleached one. All materials were ground in a blender before use. Water and ash contents were determined gravimetrically, according to international standards. Samples were suspended in 0.05 M sodium citrate buffer, pH 4.8, to obtain an initial solids concentration of about 5 g.L⁻¹ (dry basis). A mixture of two commercial enzyme preparations was added: cellulase 2.25 mL.L⁻¹ (Celluclast 1.5 L), and cellobiase 1.13 mL.L⁻¹ (Novozyme 188). Samples were incubated at 50 °C in an orbital shaker at 250 rpm for 24 h. This hydrolysis time was selected based on a recent study that has demonstrated little effect of time on the process yield over 24 hours [9]. Tests were performed in triplicate for each sample and the concentrations of reducing sugars were estimated by the dinitrosalicylic acid method.

Results and conclusions: Recycled paper sludge presented high contents of moisture (66.2%) and ash (20.6%, wet basis). Inorganic fraction probably includes additives such as kaolin, calcium carbonate and titanium dioxides, as well as metals from printing inks. Moisture and ash fractions were around 7.0% and 0.3% for bleached pulp and 22.5% and 1.1% for unbleached pulp.

Cellulose conversions estimated from the hydrolysis trials were: 82.1% for the bleached pulp, 69.5% for the sludge and 27.2% for the unbleached pulp. As expected, the sample that was not subject to the bleaching process showed lower susceptibility to hydrolysis, probably due to its higher residual lignin content that hinders the enzyme action. The other materials showed relatively high saccharification efficiencies because they have already been “pretreated” during the production process itself. Although paper sludge have presented lower conversion than the bleached pulp, the presence of inorganic compounds seemed to cause no significant inhibition of the saccharification process.

Therefore, the present study suggests the technical feasibility of using the materials tested as a source of monosaccharides for ethanol production, without requiring an additional step of pretreatment. Special interest is focused in the use of sludge from the paper recycling process, adding value to this byproduct and minimizing environmental impacts.

BMC Proceedings 2011, 5(Suppl 7) P118

**Background:** The flavonoids, naringenin-chalcone and naringenin, are intermediates in phenylpropanoid metabolism in plants, occupying the central position as primary intermediates in flavonoid biosynthesis and are synthesized by chalcone synthase (CHS) and chalcone isomerase (CHI) respectively.[1] It has been reported that supplementation of naringenin-chalcone and naringenin can inhibit the activity of 4CL in vitro, and suppress the growth and reduce lignin content in gianmous plants, while 4CL suppression affected plant phenotype and resulted on dwarfed trees on *Pinus sylvestris*. Its down-regulation promoted enhanced growth phenotypes on transgenic aspens trees [3], also CHS expression controls flavonoid synthesis and reduced size phenotype on arabidopsis.[4] Eucalyptus is the main source of biomass for pulp and paper industries therefore it’s imperative to study the influence of flavonoid supplementation on Eucalyptus and what kind of overall impact it can have on plant development, especially wood formation and gene expression.

**Methods:** Plant Material: 1 month Eucalyptus plantlets were divided into 3 groups with 25-30 individuals per group. Groups were given normal root induced nutritive solutions (Group 1) and added naringenin-chalcone (group 2) and naringenin (group 3). Treatment lasted 5 months with regular supplementation. Samples were then collected and properly stored.

**Histochromoechemical analyses:** Stem samples were harvested and fixed in FAA for at least 24h. Sections were double stained with 1% alcoholic Safranin O and 1% aqueous Astra Blue. Hand sectioned tissue samples from the same material were stained with Mäule reagent: 1% KMnO4 for 15 min, 2% HCl for 5 min, and 2% HN4OH solution. Sections were observed under an Olympus BX51 microscope under white light, and the images were obtained with DP-72 digital camera and Image Pro Plus 6.3 software.

**mRNA Sequencing:** RNA was extracted from xylem tissue according to [5] and mRNA libraries were prepared following instructions from the Illumina mRNA-Seq Prep Kit. Three distinct libraries were generated: *E.urograndis* plantlets supplemented with naringenin-chalcone; naringenin; and control solution, containing 34,157,958 (65.75% mapped); 33,743,449 (64.80% mapped); 32,076,198 (65.09% mapped) reads, (reads size approximately 36pb).

**Assembling and annotation:** We assembled 167,271 ESTs (130,290 from *Genolysophum* and 36,981 from NCBI) from several species and tissues using the program CAP3. [6] The assembled produced 53,412 unigenes (18,098 contigs and 35,314 singlets). All unigenes were automatic annotated using the BLAST [7], including: non-redundant (NR) database of NCBI, pfam [8]. Moreover, we performed a functional annotation using the BLAST2GO software. [9]

The RNA-Seq reads were aligned against the assembled unigenes using the SOAP2 aligner [10]. In order to perform the differential expression analysis between libraries, a normalization and statistical pipeline were applied using DEGseq software [11] considering 99% of confidence rate (cut-off of 0.01).

**Results and discussion:** Dual staining with Astra-blue and safranin-O histochromoechemical analysis show, that both groups of plants treated with flavonoids exhibit a much greater blue stain, typical of celluloses content, when compared to control plants, while exhibiting a lesser amount of the red/purple stain related to phenolics compounds. The Mäule color reaction which provides an effective method for the detection of syringyl units, show an increase of S lignin content on both group of plants supplemented with naringenin and naringenin-chalcone. mRNA sequencing shows drastic changes on genes related with flavonoid synthetics, annotated contigs for those genes presented a much lower expression than control groups. Almost all genes from the phenylpropanoidpathway presented lower expression on treated groups, with genes at the beginning of the pathway presenting the most noteworthy reduction, while genes at the end of the pathway presented higher expression on treated groups which is interesting as it can suggest a shift from guaiacyl to syringyl monolignols increasing lignin solubility. Gene Ontology annotation shows significant differences among a number of metabolic processes, including cell growth, cell division and response to stress. Among the most expressed genes were found heat-shock proteins, dehydrins and many no-hits. It is clear that supplementation with flavonoids alter gene expression especially regarding lignin biosynthesis.

BMC Proceedings 2011, 5(Suppl 7) P119

**Background:** Lignin is the main impediment for efficient cellulose extraction and ethanol production from woody tissues. Even though, the biosynthesis of the lignin constituents - the monolignols - is well characterized, little is known about the genetic control of the natural variation in lignin content and composition. The few association studies performed to date in forest species only uncover 5-20% of the heritable variation of quantitative traits such as wood composition. The “missing heritability” can be explained in part by the low resolution of these pioneering association studies in forest species. However, as observed in genome-wide association studies with humans, a large proportion of the “missing heritability” is likely to occur due to other factors, such as the
abundance of rare alleles observed in forest species and complex epistatic interaction between genetic elements. Causal rare alleles and genetic interactions remain undetectable with current statistical methods. In order to shed light on possible interactions between lignin biosynthesis genes and other pathways, we analyzed the transcriptome of 181 genotypes of a pseudo-backcross family of *Populus*. The analyses allowed identification of genes and pathways that were highly co-expressed with genes involved in the biosynthesis of monolignols. Correlations at the transcript level offer initial evidence of possible interactions between genetic elements for the production of monolignols.

Methods: A previously published microarray data [1] was utilized. Briefly, this microarray contains a gene expression probe for every gene annotated in the genome of *Populus trichocarpa* (v1.1.). Microarray chips were hybridized with cDNA synthesized from xylem tissue of 181 genotypes from a pseudo-backcross pedigree of *Populus trichocarpa* × *P. deltoids*. This family was also analyzed for lignin content on xylem tissue [2]. Genetic differences in gene expression allowed us to correlate the transcript abundance of 23 previously identified xylem-specific monolignol genes [3] against the cDNA levels of all annotated genes of *Populus*. Correlation was estimated based on Spearman’s rank method in R. The top correlated genes (r > 0.75, p-value <0.001) were clustered with the 23 monolignol biosynthetic-genes based on a “Modulated Modularity Clustering” method [4]. The genes clustered with the 23 monolignol biosynthetic-genes were GO annotated based on the BlastP best hit against the *Arabidopsis* gene models. A Fisher’s exact test was applied to identify GO terms enriched within these clusters. Results: Utilizing a correlation threshold of 0.75 (p-value < 0.001), 1369 genes were correlated with at least one of the 23 monolignol biosynthetic-genes. These genes were clustered together with the lignin phenotypic trait and 78 genes that were correlated with lignin (r > 0.45). The 23 monolignol genes were clustered in four groups, containing a total of 936 genes (Figure 1). Surprisingly, the lignin trait itself did not cluster with any other gene, and the vast majority (75%) of the top 78 lignin-correlated genes were grouped on clusters 12 and 15. Clusters 14 and 16 did not have lignin-correlated genes. We analyzed the GO annotation among genes within the four monolignol-related clusters. A Fisher’s exact test was utilized to find GO terms enriched within these clusters when compared to all annotated genes in the genome of *Populus*. Sixty-nine GO terms were significantly enriched (FDR < 0.01) among genes clustered with the 23 monolignol genes: 11 terms are from the ontology Cellular Component (CC), 26 from Molecular Function (MF) and 32 from Biological Process (BP). As expected, most of these MF and BP terms (>65%) are related to lignin, cellulose and hemicellulose biogenesis. This high specificity indicates that even the genes with unknown MF and BP (260 of the 936 monolignol clustered genes) might be involved in cell-wall biogenesis. Enriched GO terms not directly related to cell-wall biogenesis include “drought-recovery”, “salicylic acid catabolism”, “response to cadmium ion” and “response to zinc ion”. In addition to the significantly enriched GO terms, we also constructed a co-expression network including the core, most highly correlated genes (r > 0.85) within each of the four identified, monolignol biosynthetic clusters. These networks, representing the most likely interacting genes, will be presented.

Conclusion: This work presents a set of approximately 900 genes highly co-expressed with xylem-specific monolignol biosynthesis genes. Many of these genes are currently annotated with unknown function, or are not known to be involved in cell-wall biogenesis. We offer initial evidence towards a role or interaction of these genes in the biosynthesis of lignin and possibly other cell-wall components.

References

Figure 1(abstract P119) Symmetrical correlation matrix depicting clusters of genes highly co-expressed (r > 0.75) with 23 xylem-specific monolignol biosynthetic-genes. Clusters 12, 14, 15 and 16 contain the 23 monolignol genes, as shown. Genes within these clusters were analyzed for gene ontology term enrichment. Additionally, co-expression networks were built within these four clusters.
Background: Lignin, after cellulose, is the second most abundant biopolymer accounting for approximately 15-35% of the dry weight of wood. As an important component of wood, lignin is indispensable for plant structure and defense. However, it is an undesirable component in the pulp and paper industry. Removal of lignin from cellulose is a costly and environmentally hazardous process. Tremendous efforts have been devoted to understand the role of enzymes and genes controlling the amount and composition of lignin to be deposited in the cell wall. However, studies on the impact of downregulation and overexpression of monolignol biosynthesis in model species on lignin content, plant fitness and viability have been inconsistent. Recently, non-coding RNAs have been discovered to play an important role in regulating the monolignol biosynthesis pathway genes [1-3]. Non-coding RNAs represent an emerging class of riboregulators, which are processed to shorter miRNAs or siRNAs. The current paradigm indicated that plant system use small RNAs (miRNAs and siRNAs) as guide for post-transcriptional gene silencing and epigenetic regulation. Although miRNAs and siRNAs result from different biogenesis pathways but both interact with target transcripts for direct cleavage or translation repression, effectively shutting down that genes’ functions. However, much less is known about the mechanism of gene regulation governed by these small RNAs in lignin biosynthesis pathway in A. mangium.

Methods: Total RNA was isolated from secondary xylem tissue with contrasting lignin content using mirVana microRNA Isolation Kit (Cat. AM1561, Ambion, Austin, TX, USA) following manufacturer’s protocol. Thin cookies were first ground in a blender and then further ground to fine powder using mortar and pestle. Integrity of the isolated Total RNA was analyzed using Bioanalyzer 2100 (Agilent Technology, Palo Alto, USA) and only Total RNA with RIN value above 7 was selected for library construction. Library construction, sequencing and bioinformatics pipeline analysis was done by Gene Pool Sequencing Centre, United Kingdom. Small RNA libraries were generated using DGE small RNA Sample Preparation Kit (Cat. # FC-102-1009, Illumina, San Diego, CA, USA). Illumina sequencing libraries were prepared using the ‘long’ Illumina protocol according to the manufacturer’s direction and two libraries were sequenced on an Illumina GA-II following manufacturer’s instructions. After masking of adapter sequences and removal of contaminated reads, the clean reads were filtered and the resulting oligos were totalled. Clustering based on relative lengths from 7 nt to 35 nt were done using in house perl scripts. The targets were extracted by in house python script and annotated using BLAST to GO database. Only highly conserved miRNAs with strong differences in their expression level between high and low lignin secondary xylem were selected for validation using IQS real time – PCR technology (BioRad, Hercules, USA) (Table 1).

Results: A total of 14,582,383 reads were generated in Am54 and 5,483,383 reads in Am48. These sequences were analyzed using Bioanalyzer 2100 (Agilent Technology, Palo Alto, USA) and only Total RNA with RIN value above 7 was selected for library construction. Multiple small RNA libraries were generated using DGE small RNA Sample Preparation Kit (Cat. # FC-102-1009, Illumina, San Diego, CA, USA). Illumina sequencing libraries were prepared using the ‘long’ Illumina protocol according to the manufacturer’s direction and two libraries were sequenced on an Illumina GA-II following manufacturer’s instructions. After masking of adapter sequences and removal of contaminated reads, the clean reads were filtered and the resulting oligos were totalled. Clustering based on relative lengths from 7 nt to 35 nt were done using in house perl scripts. The targets were extracted by in house python script and annotated using BLAST to GO database. Only highly conserved miRNAs with strong differences in their expression level between high and low lignin secondary xylem were selected for validation using IQS real time – PCR technology (BioRad, Hercules, USA) (Table 1). Although these four miRNAs belong to four different families were up regulated in tension wood (Fig. 1). Tension wood is composed almost entirely of cellulose while compression wood is rich in lignin. We will further investigate the effects of over expression of these four highly conserved miRNAs in tension wood on the expression level of monolignol biosynthetic pathway genes.

Conclusions: From the sequence results, we concluded that A. mangium small RNAs consist of a set of 14 highly conserved miRNAs families found in plant miRNA database, 82 novel miRNAs and a large proportion of non-conserved small RNAs with low expression levels. Out of these 14 highly conserved miRNAs families, only four miRNAs families were selected for validation in compression wood and tension wood and their total relative counts between Am54 and Am48 are shown (Table 1). Although these four miRNAs belong to different families, all of them were up regulated in tension wood, a region composed entirely of cellulose. The results obtained can be used to better understand the roles of small RNAs and for the development of a gene constructs for silencing of specific genes involved in monolignol biosynthesis with minimal effect on plant fitness and viability.

Toward identifying molecules responsible for the peculiar properties of the G-layer in tension wood fibres

Fernanda Guedes, Miyuki Takeuchi, Françoise Laurans, Gilles Pilate*  
INRA, URS88 Amélioration, Génétique et Physiologie Forestières, F-45075 Orléans cedex 2, France  
E-mail: pilate@orleans.inra.fr  
BMC Proceedings 2011, 5(Suppl 7)P121

**Background:** Due to its peculiar properties, tension wood formation constitutes a remarkable adaptation mechanism, that makes possible for the tree to reorientate its axes (stem and branches) in response to environmental cues. In poplar, tension wood fibres harbour an extra cell wall layer, the G-layer, responsible for the peculiar mechanical properties of tension wood. This G-layer is very thick, most likely devoid of lignins and strongly enriched in highly crystalline cellulose. In addition, cellulose microfibril orientation is almost parallel to the fibre axis. We aim to identify molecular actors responsible for the tensioning of cellulosic microfibrils and we choose as candidate, molecules containing complex carbohydrates, such as pectin and the glycosylated part of arabinogalactan proteins. Indeed, a wide array of different carbohydrates has been recently evidenced in the G-layer, suggesting the occurrence of complex polysaccharides other than cellulose within this layer (1, 2).

**Material and methods:** As a first step, we realized a comparative study between tension and opposite wood fibres using immunocchemistry. A number of antibodies raised against different polysaccharide epitopes were assessed.

**Results:** The study revealed important differences in the distribution of the labeling with the kind of wood, the cellular type and within a single fibre between the different cell-wall layers. When using AX1 antibody directed against arabinoxylans, the secondary cell wall layers exhibit a very strong labeling whereas G-layers were completely devoid of labeling (3). With LMS antibodies (directed against (1-4)galactans, opposite wood is mainly labeled at the primary wall (Figure 1A), whereas in mature tension wood the G-layer is strongly labeled (Figure 1B) as already observed by (4). With JIM14 antibody directed against cellulose surface arabinogalactan-proteins, a uniform but moderate labeling was visible on the middle lamella and primary cell wall of fibers, ray-cells and vessels from both opposite and tension wood. In addition, a strong labeling appears at the inner surface of the G-layer (5). The labeling of antibodies directed against the protein moiety of poplar fasciclin-like arabinogalactan proteins are also detected in the G-layer forming fibres, and mainly at the inner surface of G-layers whereas this labeling is hardly present on primary walls which were labelled with JIM14. With CCRC-M7 antibodies directed against Rhamnogalacturonan I, the labeling is restricted to the G-layer of young tension wood fibres and more specifically to the inner face of the G-layer.

**Conclusion:** Our results strongly suggest the involvement of pectin and arabinogalactan proteins in the building of the G-layer.

E-mail: lentenberger@ufl.edu

**BMC Proceedings** 2011, 5(Suppl 7)P122

**Background:** Improvement of plant feedstock for bioenergy production can be achieved by modifying wood chemical properties and increasing biomass productivity. We previously identified a candidate gene for carbon partitioning and growth on chromosome 13 (cpg13) of poplar. Cpg13 was identified as the regulator of carbon partition and growth within a QTL interval that explains 56% of the variation in cellulose to lignin ratio, as well as 20-25% of the heritable variation in biomass. Putative homologues of cpg13 in Arabidopsis are annotated as proteins of unknown function; therefore, the functional characterization of cpg13 is essential. At present, evidence of the functional role of cpg13 is being obtained by the analysis of poplar transgenic plants transformed with RNAi, overexpression and GFP-fused – cpg13 constructs. Preliminary data indicates that down-regulating cpg13 positively impacts growth, while a negative effect is detected in lines overexpressing cpg13. Transgenic poplar 3SS::cpg13:GFP shows localization in cell wall, consistent with in silico predictions. Comparative genomics indicate moderate similarity with methyltransferase. Analysis of the impact of differentially regulating cpg13 on lignin and cellulose is currently under way in the mutants. Furthermore, attempts to purify the cpg13 protein are in progress, to define its role through a series of biochemical function assays.

**Figure 1(abstract P121)** A: in opposite wood, LMS labeling is restricted to the primary cell wall. B: strong labeling of the G-layer in mature tension wood fibres.
Secondary growth and the development of woody tissue is a key process in the formation of woody biomass. The gene family of Class III HDZip genes has been shown in the herbaceous Arabidopsis model to play a central role in regulating polarity and vascular development. While Arabidopsis is a poor model for investigating processes of wood formation, in this project all poplar Class III HDZip genes were cloned and expressed in hybrid aspen as a tree model system. To circumvent an endogenous regulation mechanism involving microRNAs the sequences were also mutated to render them microRNA resistant. Lines expressing the mutated Poplar ortholog of the Arabidopsis Revoluta gene (Populus Revoluta PRF) show a spectacular phenotype with stunted growth, radialized and rolled leaves, and a double and at times triplication or quadruple layer of the xylem, suggesting the formation of multiple layers of cambium. ClassIII HDZip genes have thus been shown to be crucial for the formation of lignified tissue in trees.

Transgenic aspen and birch trees for Russian plantation forests

Konstantin Shestibratov*, Vadim Lebedev, Alexey Podrezov, Margarita Salmova
Branch of Shemyakin and Ovchinnikov Institute of Bioorganic Chemistry RAS
E-mail: shestibratov@rambler.ru
BMC Proceedings 2011, 5(Suppl 7):P124

Background: Aspen (Populus tremula) and birch (Betula pubescens) are the fast-growing trees successfully used for the aim of plantation forestry. These species have the great potential in Russia to meeting the need for paper, timber and other wood-based products. However, enhanced growth rate, decreased lignin content and herbicide resistance are the required properties of new trees for plantation forestry. Breeding of forest trees is a slow process due to the long generation intervals typical of most forest trees and because many traits can only be properly assessed at rotation age. Genetic modification is an alternative method that can be used for new trees creation.

Methods: Genetic transformation experiments were carried out using vectors pBI-4CL, pBI-Xeg, pGS and pBIBar and supervirulent Agrobacterium tumefaciens strain CBE21. pBI-4CL plasmid contains the expression cassette harboring inverted fragments of 4-coumarat-CoA-ligase gene (GenBank AY043494). pBI-Xeg vector was constructed using cDNA of xyloglucanase gene cloned from Penicillium canescens. pGS and pBIBar vectors contain pine glutamine synthetase gene (GS) and phosphinothricin acetyltransferase gene (bar). For transcription control of expression 35S promoter used in all cassettes harboring the gene of interest. Internodes from in vitro aspen plants (Populus tremula) and leaves from in vitro birch plants (Betula pubescens) cultivating on WPM medium were used as an explants for Agrobacterium-mediated transformation [1,2]. Transformed shoots selected on the modified MS medium with 25 (aspen) or 50 (birch) mg/l kanamycin.

To detect DNA fragments from binary vectors transformants were analysed by PCR. Expression of recombinant genes was detected by RT-PCR. Lignin content determination performed by using the Klason method.

Results and conclusions: As a result of two Agrobacterium-mediated transformation experiments with pGS vector 56 and 27 transgenic lines of birch and aspen have been produced respectively. Presence of recombinant glutamine synthetase GS gene confirmed by PCR in 52 birch and 23 aspen lines. GS gene expression at the RNA level demonstrated RT-PCR analysis (Figure 1). Most of GS lines have resistance to subletal dose of phosphinothricin as well as in the in vitro and greenhouse conditions. Comparative biometric analysis of GS plants in a greenhouse makes it possible to select 7 and 3 superior lines of birch and aspen respectively. Growth rate enhancement of selected lines was 20-25%.

Genetic transformation of aspen plants for 4-coumarat-CoA-ligase gene down-regulation and xyloglucanase overexpression has been performed.

Figure 1(abstract P124) RT-PCR analysis of a glutamine synthetase gene expression in transgenic aspen plants: + and – are RNA preparations with or without the treatment with reverse transcriptase, respectively; K+ is pGS plasmid; f2 is nontransformed control; M - molecular marker.
using pBI-4CL and pBI-Xeg binary vectors respectively. 11 transgenic lines with inverted fragments of 4CL gene and 15 lines harboring Xeg1 gene have been produced. DNA fragments of 4CL RNAi-construct were detected in all lines. 14 out of 15 transformants produced with pBI-Xeg vector harboring Xeg1 gene. Chemical analysis of stem wood of 4CL lines demonstrated decreased lignin content (Table 1). Lignin reduction from 11 to 23% was achieved. Line PtXIII4CL2 demonstrated minimum lignin content 18.7%. Color modification of stem wood was observed for 8 out of 11 4CL lines (Figure 2).

Aspen and birch transgenic plants with bar gene coding resistance against herbicide phosphinotricin were also created. Transformation experiments were carried out using vector pBBar. 19 aspen and 9 birch lines were selected as a result of transformation. Presence of bar gene was confirmed in all lines. Herbicide resistance was observed at 16 and 7 lines of aspen and birch respectively. Lines tested in a greenhouse demonstrated normal phenotype without somaclonal variations and may be recommended for the field trials.

To combine several new properties in one plant the co-transformation method was developed. This method allows transferring recombinant DNA fragments from three T-DNAs of two plasmids independently [3]. Efficiency of co-transformation was up to 100%. Currently we attempt to apply this method for the production of superior aspen and birch plants with enhanced growth rate, decreased lignin content and herbicide resistance at the same time.

BMC Proceedings 2011, 5(Suppl 7):P125

Background: Real time quantitative reverse transcription PCR (real-time qRT-PCR) is an established technique for quantification of mRNA and has been extensively used for gene regulation studies in plants. However, there are inherent challenges associated with the technique such as variability of RNA and extraction protocols, different rates of reverse transcription and PCR efficiencies. This demands an accurate method of normalization to obtain reproducible results. Among the various methods, normalization to a reference house keeping gene is the most commonly used method. If inappropriate reference genes are used for normalization, the experimental results can vary significantly leading to false results [1]. Eucalyptus camaldulensis Dehn., is a widely distributed tree species used for planting in arid and semi-arid areas. The wood is composed of mainly cellulose and lignin and the pathway involved in lignin formation is fairly understood. The lignin biosynthetic genes Ferulate 5 Hydroxylase (F5H), 4 Coumarate CoA Ligase (4CL), Cinnamoyl CoA Reductase (CCR) and Cinnamoyl Alcohol Dehydrogenase (CAD) are highly conserved across the tree species and have been utilized as targets for manipulating lignin
content. The present study describes validation of a reference gene in various tissue types of eucalyptus and its subsequent use for the expression analysis of lignin biosynthetic genes.

Materials and methods: Samples were collected from three different tissues of *E. camaldulensis* namely xylem, young leaf and mature leaves and three developmental stages viz one, one and half and three years. The samples were named as X (1-3) for all the xylem samples coming from three developmental stages and Y(1-3) and M(1-3) for young leaves and mature leaves respectively (Figure 1). Total RNA was extracted with RNeaQues Kit (Ambion, Austin TX, USA) following manufactures protocol. cDNA was synthesized from 1 μg of RNA using High Capacity cDNA Reverse Transcription Kit (Applied Biosystems, Foster City, CA, USA) with random hexamer primers. Primers for housekeeping genes and lignin biosynthetic genes were designed based on the EST data from Eucalyptus using Primer Express 3.0 Software (Applied Biosystems). The nucleotide sequence of CAD, CCR, 4CL and FSH from *E. camaldulensis* were deposited in NCBI database (HR309064, HR309065, HR309066, HR309067). The real time PCR efficiency of each primer pair was determined with the slope of a linear regression model and all PCRs displayed efficiencies between 90 and 95%. Comparative C<sub>T</sub> method was followed for quantification of lignin biosynthetic genes with 18S rRNA as the internal control as suggested by Schmittgen and Livak [2]. The stability analysis of each reference gene was carried out by the method given by Brunner et al [3].

Results: The choice of internal control is usually straightforward for analysis of samples from same tissues. However, when samples are derived from different tissues or developmental ages, as it is seen in our study, required validated reference gene/genes. Six different housekeeping genes were chosen for the analysis which included GAPDH, Beta glucuronidase, protein L7, Translational initiation factor (TIF) and Glyceraldehyde 3 phosphate dehydrogenase. Among the genes used in the study, 18S rRNA showed the least C<sub>T</sub> indicating higher abundance while the highest C<sub>T</sub> was observed for TIF. Further, 18S rRNA showed maximum stability when C<sub>T</sub> was plotted against samples (Figure 1). A gene with low stability index is considered to have highest stability [3]. In the present study with *E. camaldulensis*, 18S rRNA had the lowest stability index while GAPDH showed most variation among the samples.

Expression analysis of four lignin biosynthetic genes viz CCR, CAD, FSH and 4CL were carried out in different samples by using 18S rRNA as the reference gene. Lignin analysis of samples showed higher lignin content in three-year-old samples estimated by klosn lignin analysis compared to one-year old. All genes under study showed increased expression in three year old samples except for CAD gene. The results also showed increased amount of FSH transcripts in older tissues indicating higher syringyl units in older tissue. Chen et al [4] reported syringyl type lignin content and S/G ratio increased from younger internode to older internode while G and H decreased in parallel.

As the expression profile showed variations in different age samples, further experiment was under taken to evaluate the expression levels of these genes in same age trees (Three year old) in correlation with lignin content. Based on klosn lignin content, trees with lignin content of 26± 0.3 and 24± 0.2% were chosen for the studies. All genes under study viz4CL, CAD, CCR and FSH showed increased in expression in high lignin sample in comparison with low lignin.

Conclusions: Among the house keeping genes under study, 18s rRNA exhibited lowest stability index and we are suggesting it as a reference gene for expression studies in Eucalyptus. The reduction in CAD transcript level and higher levels of FSH in older tissues indicated a possible shift towards an increased syringyl lignin where as when analysis was done at same age, expression levels of all selected lignin biosynthetic genes were high in high lignin tree. The study opens up the possibility for using these genes as candidate genes for the selection of desired genotypes.

Acknowledgements: The first author would like to thank Ramadevi P for lignin analysis and Girisha R in helping in statistical analysis.

BMC Proceedings 2011, 5(Suppl 7):P127

Background: Somatic embryogenesis (SE) is the only clonal propagation method that has potential for large scale production of conifer plants from the breeding programs. Methods that support bioreactor-based methods for SE propagation are developed [1,2]. Samples of somatic embryos can be stored indefinitely under liquid nitrogen for future plant production. Somatic embryo cultures are also studied as model systems for conifer embryo development to address fundamental research questions, or used as material for genetic transformation to study gene function in conifers.

In addition to utilizing SE for masspropagation of known elite clones previously tested in field tests, the SE technology offers an opportunity to directly capture and increase the value of small samples of elite seeds from the breeding programs. Furthermore, by direct masspropagation of families through SE, the value of the elite seed is increased; however without the cost of clonal testing. This is arguably an alternative approach to the traditional approach of only utilizing clonal field-tested material for SE masspropagation [3]. The aim of this project was to investigate the effect from seed storage time on the rate of somatic embryo initiation for the purpose of optimizing the use for SE over time of small valuable seed samples. This was done by isolating ZE from seeds of Norway spruce that had been stored for various times, and were collected from different parts of Sweden.

Results:
All 19 seed batches showed SE initiation however at different frequencies. The highest initiation frequency related to the time in storage. The seeds tested had been collected from different parts of Sweden. There was also no difference in initiation frequency related to the time in storage.

Materials and methods:

Plant material: Nineteen batches of Norway spruce (Picea abies) seeds from commercial seed orchards in southern, middle and northern parts of Sweden were provided by the forest companies supporting the project.

Initiation of Somatic Embryogenesis: The spruce seeds were sterilized with 95% ethanol followed by 30% (v/v) commercial bleach and Tween 20. The bleach was discarded and the seeds were rinsed three times with sterile distilled water and left to imbibe overnight at room temperature. After imbibition, ZE were dissected from the female gametophyte under a dissecting microscope and cultured on half-strength LP medium supplemented with 10 μM 2, 4-Dichlorophenoxyacetic acid and 4.4 μM Benzyldenamine for SE initiation. In total 90 ZE were isolated from each seed batch. The SE initiation was monitored on weekly basis.

Maturation of Somatic Embryos: One cell line per seed batch was tested for embryo differentiation from pro-embryogenic masses (PEMs) on DKM containing no plant growth regulators (PGRs) and maturation on DKM supplemented with 30 μM Abscisic acid.

Results: In total we tested 19 seed batches of Norway spruce where 90 ZE were isolated per seed batch and placed on ½ LP medium containing PGRs for SE initiation. Three weeks after isolation of ZE, callus formation was observed. Embryogenic callus is composed of PEMs that have a white and translucent appearance (Fig. 1) and are mostly produced from the hypocotyl region of the ZE. When whitish callus reached a size of 5x5 mm, it was isolated from primary explants and placed on proliferation medium for continuous growth.

All 19 seed batches showed SE initiation however at different frequencies (Fig. 2). The initiation frequency did not vary notably between the seeds from different parts of Sweden. There was also no difference in initiation frequency related to the time in storage.

Figure 1(abstract P127) SE initiation from zygotic embryo of Norway spruce. ZE extracted from spruce seeds produced PEMs after 3-4 weeks in culture.

Acknowledgments: Funding for this research was provided by Genomica Forestal (INNOVA-Chile, CORFO) and FONDEF 031103.
PEMs could produce mature somatic embryos. We observed that 11 out of 19 tested cell lines produced mature somatic embryos (data not shown). Since only one cell line from each seed batch was tested for maturation, we cannot exclude that the remaining 8 seed batches were capable of producing mature somatic embryos. However, similar to the initiation process, the maturation stage did not appear to be related to the storage time and the geographical origin of the seed.

Conclusion: We have demonstrated that it is possible to propagate small batches of Norway spruce seeds stored for up to 25 years through somatic embryogenesis. All initiated cell lines established cultures of PEMs and most cell lines tested produced mature somatic embryos. Thus we conclude that SE can provide a promising method for amplifying small valuable batches of elite seeds even if the seeds have been stored for up to 25 years.

Acknowledgements: We thank the Swedish Research Council (VR) and the Swedish Governmental Agency for Innovation Systems (VINNOVA) for financial support. We are grateful to Sveaskog, Bergvik, Holmen and Södra Skogsägarna for supplying the seeds and Edward Businge for his contribution during the experimental part of this project. Ifthikar Ahmad and Sofie Johansson contributed equally to the work.

Somatic Embryogenesis as a tool for forest tree improvement: a case-study in Eucalyptus globulus
Gisele Andrade1, Ravi Shah1, Sofie Johansson1, Gloria Pinto2, Ulrika Egertsdotter1
1Department of Forest Genetics and Plant Physiology, Swedish University of Agricultural Sciences, Umeå, 90187, Sweden; 2Centre for Environmental and Marine Studies (CESAM) & Department of Biology, University of Aveiro, 3810-193, Aveiro, Portugal
E-mail: Gisele.Andrade@slu.se

Background: Somatic embryogenesis (SE) technology is expected to play a significant role in future forest tree improvement programs. Methods for efficient SE propagation in softwood species based on bioreactors are underway [1]. Furthermore, genetic transformation through SE is also the most promising approach to generate and propagate elite recalcitrant genotypes of forest trees [2], or clonal propagation of selected endangered high-value forest trees [3,4].

Somatic embryogenesis induction was first reported for the genus Eucalyptus in 1980. Mass production of SE plants however remains
difficult although procedures designed for plant regeneration have been reported for *E. citriodora, E. grandis, E. tereticornis* [5]. Recent data on *E. globulus* are promising and show the potential of this technology for application in clonal forestry [6,7].

A service platform for routine transformation of forest trees has been established at the Berzelii Center at Umeå Plant Science Centre using Norway spruce as the primary model species for gene function analyses. Other target species for future studies include hardwood species such as Poplar and Eucalyptus. We present here a brief summary of a case study for introduction of a recalcitrant forest species to the platform as demonstrated by the establishment of the SE technology for *E. globulus* following protocol previously established in Portugal [6] and preliminary results aiming to improve the induction of SE.

**Material and methods:** Half-sib seeds of *E. globulus* collected from trees in Portugal (Altri Florestal Breeding Program) were used in this study. Seeds were surface-disinfected with a mixture of 1:1 absolute ethanol: hydrogen peroxide 30% (v/v) for 15 minutes. Two sources of explants were tested: (a) cotyledons and hypocotyls isolated from 15 day-old in vitro seedlings germinated on standard MS medium and (b) zygotic embryos (ZE) isolated after removal of the seed coat. Briefly, using a standard protocol [7], explants were inoculated on induction medium (MS<sub>nana</sub>) consisting of MS with 3 mg/l NAA, 30 g/l sucrose, 2.5 g/l Gelrite, pH 5.8. Cultures were incubated in the dark at 24 °C for 25 days. After this period, explants were transferred to the same MS medium without NAA (expression medium M<sub>exp</sub>) under the same conditions.

To evaluate the effect of factors indicated from previous studies as essential for the process of SE induction, we then tested the effect of media composition using only 2E as explants: induction and expression using MS salts but containing other vitamins (MS, BS and RP) and 5 days induction on MS containing 5 mg/l NAA or 2 mg/l 2,4-D and the remaining 20 days on MS<sub>nana</sub>. Embryogenic potential was analyzed under the microscope and the results expressed as the percentage of explants showing somatic embryos. Callus production and root formation were also scored.

**Results:** Adopting a standard protocol, the source of explants affected the SE induction as previously reported for other species: no embryogenic response was observed and only callus and root formation occurred when cotyledons and/or hypocotyls was used as source of explants (data not shown); 5-20% of the explants showed formation of globular somatic embryos after transferring to expression medium within 5-8 weeks after induction when 2E was used. The present study included the same OP families previously tested in Portugal. The induction rates rated in a similar way to the previous study, confirming the importance of the genotype.

Preliminary results from the evaluation of factors affecting SE inductions show that root and root hair formation was observed on most of the explants in all tested treatments. Adding different vitamins to the MS medium showed the same embryogenic response. When 2E were cultured for short period on medium containing 2,4-D or 5 mg/l NAA, almost 100% of the explants showed callus formation. However, the embryogenic response was similar to the control treatment indicating that concentration/induction period should be adjusted and/or other PGRs combinations tested in the future.

Individuals or small clusters of globular embryos were isolated and transferred to MS<sub>nana</sub> for capture of embryogenic cultures. The most developed somatic embryos isolated displaying a shoot and tap root were transferred to M<sub>exp</sub> for plant conversion.

**Conclusion:** The data reported here show the reproducibility of the previously published protocol using different genotypes of *E. globulus*. The results also indicate the importance of genotype over culture condition for the induction success. New experiments are in progress aiming to increase the induction of SE and establish an efficient protocol that can form the basis for genetic transformation of hardwood SE cultures.

**Acknowledgements:** We thank the Swedish Research Council (VR) and the Swedish Governmental Agency for Innovation Systems (VINNOVA) for financial support. We are grateful to Lucinda Neves and Clara Arajuo at Altri Florestal Breeding Program for supplying the seed batches. Ravi J. Shah is the primary technical research assistant for this project.

Testing of candidates as clones would greatly benefit breeding of Scots pine (*Pinus sylvestris* L.), but has not been applied because of vegetative propagation of the species is difficult. With a common interest in Scots pine breeding, forest research institutions from Sweden, Finland, and Latvia (Skogforsk, Metla, and Silava, respectively) joined in a collaborative project to develop pine cutting propagation for breeding purposes. The main objective of this effort was to find protocols for efficient shoot propagation, and at the same time, maintain a high rooting response. Secondly, the aim was to increase the knowledge on the influence of different rooting agents, watering regimes and substrates on the rooting of cuttings.

From Finland and Latvia, respectively, 15 full-sib families from parents with high breeding values were included. From Sweden, 15 families from each of two research stations, one northern and one southern, were included. These sets of the families were used locally. Another collection of five families was shared among the participants, which means that 5 families extra were included at each location. All donor plants were pruned the same way. However, the timing of the pruning varied in the five propagation models tested:

- **A.** One-year-old donor plants pruned to yield 2x winter cuttings / 4-year method
- **B.** One-year-old donor plants pruned to yield winter cuttings and late summer cuttings / 3-year method
- **C.** "Turbo line" i.e. one-year-old donor plants pruned 2x cuttings in one year / 2-year method
- **D.** One-year-old donor plants pruned to yield 2x late summer cuttings / 3-year method
- **E.** Two-year-old donor plants pruned to yield winter cuttings / 4-year method

According to the results, the average production of cuttings with propagation models including two harvests in consecutive years on the same donor plant can be predicted to be 10-15 cuttings per a donor plant, with a substantial variation among families and donor plants. Even though rooting responses above 50% can be achieved, this could not be repeated for a large number of propagations. The generally low and erratic rooting responses leads to conclusion that the project was unsuccessful in developing improved and reliable protocols for Scots pine cutting propagation. However, a propagation model enabling two harvests on a 1-year-old donor plant within the same year is a promising option but needs further studies.

Gene expression patterns associated with developmental transitions during somatic embryogenesis in pine
Elena Carneros*, Inmaculada Hernández, Silvia P Solana, Carmen Díaz-Sala, Dolores Abearca
Department of Plant Biology, University of Alcalá, Alcalá de Henares, Madrid, 28871, Spain
E-mail: elena.carneros@uah.es
BMC Proceedings 2011, 5(Suppl 7):P130

The low regeneration capacity of forest species is one of the major limitations for vegetative propagation [1]. The molecular mechanisms that determine the efficiency of clonal propagation programs via either adventitious organogenesis or somatic embryogenesis have not been established. For clonal propagation via somatic embryogenesis, the success of the process depends on an initial reprogramming step and on further developmental transitions involved in the maturation of somatic embryos [2] . The identification of candidate genes involved in the regulation of key steps of the regeneration processes is essential to generate tools and strategies to improve the success of clonal propagation programs in forest species. The aim of this work is to identify new candidate genes potentially involved in the regulation of developmental transitions in somatic embryogenesis in pine. For that purpose, samples of embryogenic tissue from Pinus radiata D. Don at different stages of development were used: proliferative tissue (after 7 and 14 days from the last transference to fresh proliferation medium), somatic embryos at the beginning of differentiation and somatic embryos at cotyledonary stage [3,4]. Large-scale expression analysis using a microarray containing an EST collection enriched in auxin-induced genes, and several tissue-specific cDNA libraries from meristematic and embryonic tissues, were used for the identification of phase-specific candidate genes. Genes related to auxin signaling, regulation of gene expression, signal transduction, proliferation and embryo development were selected for further analysis. The expression of these candidate genes was confirmed by QRT-PCR. The information obtained from this work will open new ways of research on molecular mechanisms involved in developmental processes in conifers. This work was funded by the Spanish Ministry of Science and Innovation (AGL-2008-05105-C02-01/FOR). Embryogenic lines were provided by C. Walter (Giron). References

Development of micro-propagation and mini cutting protocol for fast growing Melia, Dalbergia and Eucalyptus clones for pulpwood and bio-energy plantations
Senniappan Chinnaraj*, C Malayuthu
S.V. Subrahmanyam Tamil Nadu Newsprint and Papers Ltd, India
E-mail: chinnaraj@tnpl.co.in
BMC Proceedings 2011, 5(Suppl 7):P131

Per capita paper consumption is only 9.2 kg in India, which is much lower when compared to other neighboring developing economies, such as, China (42 kg) & Indonesia (23 kg). Currently Indian economy is growing by 7.5% per annum. Along with economical growth, the paper demand is also expected to grow and cross 20 million tonnes per annum by 2020 from current 10 million tonnes. Availability & quality of raw material, non availability of land for pulp wood plantations, alternate use of pulp wood for other uses like bio-energy and regulations to increase green energy use in mill operations would become major challenge for Indian paper industry’s survival and growth. To face these changes effectively, paper industries in India initiated many social forestry models and brought 4,00,000 hectares under pulp wood plantations. This has helped pulp wood availability and reduced the fibrous raw material shortage to some level but it is not enough to meet the growth. Tamil Nadu Newsprint and Paper Limited (TNPL) is state owned integrated pulp and paper industry situated in southern most state of India and produce around 4,00,000 tons of paper per annum. TNPL has 300 Tonnes per day (TPD) hardwood fibreline along with 550 TPD bagasse fibre line to meet its pulp requirement. TNPL had setup biotechnology and bio-energy research facility under the existing R & D Department to work on identification, selection and multiplication of improved pulpwood clones of Eucalyptus and other alternate fast growing hardwood species through modern biotechnological methods to meet pulpwood and also bio-energy need. The plant tissue culture facility has one million plants per annum capacity and optimized protocols for many improved Eucalyptus pulp wood clones to use as clonal mother plants at Clonal Production and Research Centre of Plantation Department using mini cutting process. TNPL clonal production facility has capacity of 15 million seedlings per annum and already covered 52,000 acres of pulp wood plantation and plan to cover additional 15,000 acres every year.

As a part ongoing research activity, one Melia dubia clone for bio-energy/pulpwood and one Dalbergia sissoo clone and three clones of eucalyptus, (each one from E. urograntis, E. tereticornis, and E. camaldulensis), were identified based on its biomass productivity, as well as, pulp quality and yield. Micro-propagation protocol was optimized for all the above five clones with modified MS medium with various concentrations of cytokinin and auxin. The seedlings produced using micro-propagation were used as mother plants for clonal mini garden in the concrete sand beds where the nutrient requirements where optimized for further multiplication using mini cutting process. The results of above study is presented and discussed in this paper.

Wood and pulp properties of all selected Melia dubia, Dalbergia sissoo, E. urograntis, E. tereticornis, and E. camaldulensis clones are presented in the Table 1 along with reference Eucalyptus pulp wood used in the mill. All the selected clones show high yield and strength properties. However, Melia dubia is not preferred as pulpwood due to low bulk density which would result in less through-put in fibreline. But it can be exploited for bio-energy applications especially for biomass gasification to generate producer gas and use in Lime Kiln to replace fuel oil and also for other wood product applications. All the selected clones give approximately minimum 2.5% more pulp yield with improved pulp properties when compared reference pulpwood currently used in the mill. Higher pulp yield would definitely give better economy and environmental performance of mill operations. For example, 1% yield increase would result in annual savings of INR 35.0 million in pulp wood cost for mill of our size i.e. 300 TPD. Therefore, for 2.5% yield increase would result in annual saving of around INR 87.5 million apart from chemical saving and other environmental benefits.

To take all the selected clones from lab to land in a short period, micro-propagation and mini cutting protocols were optimized. The results are presented in the Table 2. E.tereticornis clone found to perform well during initiation, elongation and hardening. On the other hand, E. urograntis found to perform well during multiplication and gave maximum number of shoots per clump. All the Eucalyptus clones found to perform well during the rooting. Melia dubia and Dalbergia sissoo are found to perform poor in micro-propagation compared to Eucalyptus. Seedlings produced by micro-propagation are used for mini cutting experiments and results are presented in Table 2. E. urograntis produced more number of cuttings per plant per month followed by Dalbergia sissoo, E. tereticornis E. camaldulensis and Melia dubia. Rooting and survival rate is also high for Eucalyptus clones when compared to Dalbergia sissoo and Melia dubia. Micro-propagation followed mini cutting protocol for propagation of all the above clones has been successfully adopted by mill for commercial production of quality seedling for mill’s pulp wood and other plantation programme.

E-mail: raj.deepika@fabi.up.ac.za

**Background:** Agrobacterium mediated gene transfer technology offers the potential to introduce novel, high-value traits into selected, elite...
tree genotypes. Significant progress has been made in the regeneration and genetic transformation of Eucalyptus trees, but transformation efficiency has generally been low for eucalypts [1], especially for elite clonal genotypes. As a preliminary step towards the regeneration of explants derived from clonal material and the production of transgenic plants from commercially important Eucalyptus genotypes, there is a need to identify genotypes exhibiting high regeneration capacity. In this ongoing study, we are comparing eight Eucalyptus genotypes for callus induction and shoot regeneration potential. Browning of callus tissue and surrounding culture media is a common obstacle limiting regeneration of shoots in eucalypts. Hence, a second aim is to minimize the oxidation of phenolic compounds released from the wounded tissue and improve shoot regeneration rates.

Methods: Shoot buds collected from potted ramets of eight Eucalyptus clones (Sappi and Mondi, South Africa) were established under in vitro conditionson MS [2] basal medium containing BAP (Benzyd adenine purine). The established clones consisted of four E. grandis (G1, G2, G3 and G4), one E. grandis x E. nitens (GN1), two E. grandis x E. camaldulensis (GC1 and GC2) and one E. grandis x E. uralphilla (GU1) genotype. Leaf explants were excised from in vitro shoot cultures and cultured on MS basal medium containing BAP, NAA (Naphthalene acetic acid) and TDZ (Thidiazuron). Browning and necrosis of the callus as well as surrounding culture media was observed in all cultures and PVP (polyvinylpyrrolidone) was therefore added to the media to reduce oxidation.

A standardised regeneration protocol was used for the optimization of Agrobacterium mediated genetic transformation of selected Eucalyptus clones. The Agrobacterium tumefaciens strain AGL1 containing pMDC162 with the uidA gene (β-glucuronidase; GUS) and hpt (hygromycin phosphotransferase) gene was used for transformation. To minimize extensive exudation of phenoic compounds from the wounded explants, the leaves were subjected to different wounding methods. Intact leaves were excised from in vitro shoot cultures and preconditioned for 24 hrs on callus induction medium followed by wounding with a surgical blade prior to Agrobacterium infection. The leaves were wounded in two different ways: (a) removing the edges of the leaf, making 5-10 small wounds and cutting the leaf transversally into two equal halves and (b) making 5–6 small small wounds in the intact leaf without damaging the rest of the leaf. Alternatively, the leaves were wounded prior to 24 h preconditioning using the first wounding method (a). The explants were immersed in a bacterial solution (A600 > 0.8) for 1 hr followed by blotting with sterile filter paper. The explants were co-cultivated for 24 hrs and stained for GUS activity after two days to determine the percentage of explants showing transient GUS expression.

Results and discussion: Callus initiation was observed at the cut edges and wounded regions of the leaf explants after 20 days of incubation in complete darkness at 25 ± 2°C. Shoot regeneration was also observed on the same medium after 30 days of culture. Callus induction percentages of 76% (GU1) to 100% (G3) and shoot regeneration percentages of 3.4% (G4) to 75% (G1) were obtained from the leaf explants (Figure 1). Tissue oxidation was observed in all of the cultures when exposed to light, which hampered shoot bud development and elongation considerably. Addition of PVP to the media resulted in reduction of tissue browning and increased shoot regeneration rate ranging from 6.7% (G4) to 86.7% (G1 and GN1) (Figure 2). Browning of the tissue and surrounding media occurs due to oxidation of the phenolic compounds by polyphenoloxidase, peroxidise or exposure to air which can be reduced by the addition of antioxidants such as PVP to the culture media [3]. Based on the modified protocol including the addition of PVP, Eucalyptus grandis (G1) and E. grandis x E. nitens (GN1) exhibited the highest shoot regeneration potential (86.7%) and may serve as suitable starting material for further genetic transformation studies.

Different wounding methods did not have a significant effect on transient GUS expression in leaf explants. However, good GUS activity was detected in the transformed callus induced from the leaf explants wounded prior to preconditioning.

Conclusion: We have achieved efficient and rapid callus induction, as well as shoot regeneration for selected Eucalyptus clones. The information presented here forms the basis for ongoing optimization of a protocol for the generation of transgenic plants of clonal Eucalyptus genotypes.

**Figure 1** (abstract P132) Effect of genotype on percentage of callus induction and shoot regeneration after one month of culture on regeneration media without PVP. Callus induction rate = Number of explants inducing callus / Total number of leaf explants cultured x 100; Shoot regeneration rate = Number of calli inducing shoots/ Total number of leaf explants cultured x 100. Error bars indicate the standard error of the mean of five replicates.

**Figure 2** (abstract P132) Percentage of leaf explants exhibiting shoot bud induction after one month of culture on shoot regeneration medium containing PVP. Error bars indicate the standard error of the mean of three replicates.
expression was observed in rooting competent cuttings only. This result suggests that signaling pathways involving GRAS transcription factors and auxin distribution could be related to the regulation of age-related changes in regeneration capacity.

BMC Proceedings 2011, 5(Suppl 7):P134

Background: In vitro organogenesis is one of the key techniques associated with genetic transformation, as it determines the successful regeneration of transgenic plants after co-cultivation with bacteria. Therefore, the development of efficient regeneration protocols is the most critical step in developing genetic transformation. Protocols have been developed for several species of eucalyptus. In most of the studies cortiyyon, hypocotyls, cotyledons, hypocotyl, and leaf segments of plants cultivated in vitro are used as explants [1]. Several eucalyptus functional genomic projects have used Populus species as a model for it counts with well established regeneration and transformation protocols. However, the use of Eucalyptus clones as model plants could be more adequate, if clones with high regeneration rates as those obtained for Populus could be found. The aim of this study was to evaluate several variables in the in vitro organogenesis from leaves of an Eucalyptus sp. clone maintained in vitro at Embrapa Forestry.

Methods: The experiments were performed at the Laboratory of Tissue Culture of Embrapa Forestry, Colombo, PR. Leaf explants were collected from in vitro grown plants maintained on MS medium [2] containing 30 g L-1 sucrose, 0.88 μM BAP, 0.05 μM NAA, 0.5 μM 2,4-D and 7 g L-1 agar. The youngest leaves were cut longitudinally and placed with the adaxial side facing the media. In the first experiment, the effect of 0.5 μM thidiazuron (TDZ) was compared with different concentrations of zeatin (2.88, 4.56, 9.12 and 13.68 μM). The plant growth regulators were added to the basic medium, composed of MS salts with half of nitrogen concentration (N/2), supplemented with vitamins of Morel and Wtemore, 30 g L-1 sucrose, 0.1 g L-1 myoinositol, 0.1 μM NAA and 7 g L-1 agar. The second experiment compared the effect of MS salts N/2, WPM [3] and B5 [4] on the same basic medium described above, containing 0.5 μM TDZ. In the third experiment the effect of different concentrations of TDZ (0.25, 0.5, 0.75, 1 and 2 μM) added to the basic medium, replacing the MS N/2 by WPM was evaluated. The explants were kept in growth chamber with
controlled temperature at 23 ± 2°C in the dark for four weeks, and then transferred to the same medium after 2 weeks. After this period the explants were transferred to basal medium with WPM, 20 g L⁻¹ sucrose, 0.1 g L⁻¹ myo-inositol, 5 μM BAP, 0.05 μM NAA and 7 g L⁻¹ agar and placed under a photoperiod of 16 hours. The pH of all media was adjusted to 5.8 before autoclaving. After two months explants oxidation, callus formation, shoot formation in explants with callus and number of shoots per explants with callus were evaluated. Each treatment consisted of five Petri dishes with 10 explants. Data were analyzed by an analysis of variance. Comparisons between treatments were made by orthogonal contrasts.

**Results and conclusions:** In the first experiment, there was no callus formation or shoot regeneration on media containing zeatin in any tested concentration. These results contradict those found by [5] who observed shoot formation on leaf explants on medium containing the combination of zeatin and NAA. However, these authors have used salts formulations other than MS. In the treatment with TDZ, 10% of explants regenerated shoots. The number of shoots per callus ranged from one to more than 10. In the second experiment, BS medium was not favorable for shoot induction. All explants oxidized, although they formed small calli. In the comparison between WPM and MS N/2, in both media 6% of explants regenerated shoots. However, the WPM showed less oxidation than MS N/2. In the third experiment, where several concentrations of TDZ were compared, the number of explants with callus induction was lower in treatment with 0.25 μM TDZ (83%). In all other treatments all explants formed callus. The number of explants with shoots ranged from 7.5% in the treatment with 0.75 μM to 14% in treatments with 0.25 and 0.50 μM TDZ. Treatments with 1 and 2 μM TDZ showed 11% and 12% of calli with shoots, respectively. In E. globulus [6] observed buds induction on hypocotyls when placed on medium containing 0.05 μM TDZ and 5 μM NAA or 0.2 μM 2,4-D in. In E. saligna 40% of the calli induced on cotyledon explants regenerated shoots on medium containing 1 μM TDZ and 0.1 μM NAA [7]. Among the media tested, the WPM medium containing 0.5 μM TDZ and 0.1 μM NAA was the most suitable for *in vitro* organogenesis of the Eucalyptus sp. clone tested. However, regeneration rates (14%) are still low and further research is needed.

Herbicide resistant crops are commercially advantageous for efficient field productivity by enabling use of non-selective herbicides for weed management. Herbicide resistant trees could be used to improve productivity and reduce the costs of forest management through to the first and second years post tree establishment. We describe the introduction of the phosphinothricin acetyltransferase (bar) gene, which confers resistance to the herbicide glufosinate, into *Eucalyptus* *pelitta* (clone EP11) and hybrid *Eucalyptus* (*E. grandis* × *E. dunnii* - clone SP1383) under the control of a constitutive promoter. The transgenic lines produced showed a copy number ranging from 1 to 3 copies by Southern blot analysis. Herbicide resistance of the transgenic clones was assessed in the greenhouse by application of 200g/L phosphinothricin at the level of 6.0 L/ha and 4.0 L/ha (commercial rate). The effect of the two herbicide treatments was tested on 4-week and 6-month old plants derived from several transgenic events from the two different *Eucalyptus* clones. All 4-week old non-transgenic control plants, as well as whole shoots of 6-month old control plants were killed by the herbicide by fifteen days after application. The same herbicide treatment effectively killed all the weeds in field conditions. All the transgenic plants showed strong resistance to the herbicide in all treatments with no observed negative effects. The use of herbicide resistant trees may provide an additional means for improving the economic efficiency of plantation forest management.

Wadatsuminoki (Notaphyodes amaniamus) is an endangered tree species observed in only Amami Oshima Island located in southern part of Japan. According to the Red list published by Ministry of Environment, it is classified as 1A (Critically endangered) and naturally remaining number is only 20. It contains camptotrexin which is used for anti-cancer drugs. Kagikazura (Uncaria rhynchophylla) is an medicinal tree species observed widely in Japan and China. It contains alkaloids (rhychophylline, iso-rhynchophylline, histrine and so on) which are good for remedy of high blood pressure and dementia. For the purpose of micropropagation and development of basis of useful substance production by cell culture as well as conservation of endangered species, tissue culture procedure was developed for those two species. Excised shoots of 2 years old seedling of Wadatsuminoki rooted in the 1/20MR medium containing 3 g/l activated charcoal powder. Newly shoots were induced from in vitro root segments subcultured to 1/2MS medium containing 2µM BAP. This cycle can be used for micropropagation of Wadatsuminoki. We have succeeded in micropropagation by tissue culture of Wadatsuminoki (Figure 1). Callus proliferation from stem or root segments was observed on the 1/2LP medium containing 0.5µM BAP and 1 µM 2,4-D, this subculture cell line may be used for the possible production of secondary metabolites in vitro.

Shoots were induced from stem spine (thorn) of Kagikazura in the 1/2MS medium containing BAP or Zeatin. Regenerated plants were obtained by rooting of these shoots on 1/2MS medium containing 1 µM IBA. Callus induced around the stem segments were continuously subcultured in the fresh 1/2LP medium containing 0.5 µM BAP and 1 µM 2, 4-D. These cell lines can be used for the possible secondary metabolite production and for breeding by somaclonal variation or genetic engineering.

E-mail: jo.leonardo85@gmail.com

Background: Brazilian pine (Araucaria angustifolia (Bert) O. Ktze) is the only nanometric species with economic relevance in Brazil. Recent studies have shown due to intensive exploitation Brazilian pine was included in the official list of endangered Brazilian plants. Biotechnology tools, like somatic embryogenesis (SE), may become a potential useful tool for mass clonal propagation and ex situ conservation of commercial and endangered plant species, especially conifers. SE involves the coordinated execution of four steps (embryogenic culture (EC) induction, proliferation, maturation, and plant regeneration). As observed for other conifers, the presence of well-developed early somatic embryos (SE) in EC of Brazilian pine can be considered the pre-requisite for embryo maturation in a medium supplemented with abscisic acid (ABA) and osmotic agents. However, in some genotypes even the presence of bipolar SE does not guarantee embryo maturation. Since SE morphology cannot be used as the only factor for EC selection, the development of molecular markers for early detection of embryogenic cultures responsive to maturation promoters (ABA and osmotic agents) is highly desirable. Polyamines (putrescine (Put), spermidine (Spd), and spermine (Spm)) have been classified as plant growth regulators and hormonal second-messengers playing a critical role in various growth and developmental processes in plants, such as the differentiation and development of somatic embryos. The relation Put/Spd has demonstrated the best answers for predicting embryogenic potential in different plant species. Apart from polyamines quantification, the analysis of gene expression has been used to detect the expression of embryogenesis regulating genes like somatic embryogenesis receptor kinase (SERK), wuschel-related WOX (WOX), and ABA insensitive-1 (ABI1) during conifer somatic embryogenesis. In order to develop molecular markers for early detection of EC with high embryogenic potential in Brazilian pine, we measured the polyamine content (free and conjugate) and the expression of three embryogenesis-regulating genes (SERK, WOX and ABI1) during the proliferation phase of ECs with different maturation capabilities.

Methodology: For induction of ECs, immature zygotic embryos were inoculated in MSG medium free of growth regulators supplemented with 1.46 g L-1 filter-sterilized L-glutamine, 30 g L-1 sucrose, 3 g L-1 Gelrite (Sigma) in the dark at 25 ±2°C. After one year of EC proliferation, maturation tests were performed using MSG semi-solid medium supplemented with 120 mM abscisic acid, 9% (w/v) maltose, 7% (w/v) PEG 4000, 3% (w/v) sucrose, and 0.15% (w/v) active charcoal. All ECs were maintained in the dark at 25 ±2°C and subcultured every four weeks by transferring ECs to fresh maturation medium. Total RNA from ECs with different maturation capabilities (0.3 g fresh weight) were extracted with Trizol® (Invitrogen, Carlsbad, CA). CDNA was synthesized using 2 µg of total RNA, digested with DNase I (Fermentas), and reverse transcribed with 500 ng oligo-dT25 anchored primer (5-7T(25)WN-3) using the High Capacity CDNA Reverse Transcription kit (Applied Biosystems). Primers were designed from nucleotide sequences of Brazilian pine cloned cDNA fragments. The template CDNA were synthesized and the dilutions were adjusted with Ubiquitin 1 as an endogenous normalization factor. PCR reactions were carried out in a final volume of 25 µL and the PCR products had an average length of 175 - 200 bp. The RT-PCR products were resolved on 2% (w/v) agarose gels stained with ethidium bromide.
and photographed. The methodology for the determination of free PAs and conjugate was based on that developed by [1]. Samples (0.2 g fresh weight) were ground in perchloric acid (PCA) 5%. The conjugated forms of the PAs were obtained by hydrolysis (18 h at 110°C) in 12 N chloridric acid (HCl). The samples were then derivatized using dansyl chloride and partitioned with toluene. PAs levels were obtained by means of HPLC using a C18 reverse phase column.

Results and discussion: Despite of the maturation capability and as observed in other conifer species, the levels of free PAs in all Brazilian pine ECs tested were higher than the conjugated form, and the most abundant PA found was Put followed by Spd and Spm. However, Ecs responsive to maturation conditions (with development of mature somatic embryos) showed significantly lower Put/Spd ratios, when compared to non-responsive Ecs. A similar profile was observed in embryogenic cultures of *Oryza sativa* L. [2]. In somatic embryos of *Vitis vinifera*, an abnormal growth and a disorganized cellular proliferation were associated to an inadequate Put/Spd ratio [3].

Concerning gene analysis, only the expression of AB1 gene could be detected during proliferation phase of the Ecs cultures. Although AB1-1 gene is normally associated to events mediated by ABA [4], both Ecs responsive or not to ABA showed the expression of AB1. No expression of SERR and WOX could be detected during the proliferation phase of Ecs tested, although the expression of these genes was already detected in somatic embryos, late stage zygotic embryos and seedlings of Brazilian pine.

Conclusions: Based on our results, we can suggest that the Put/Spd ratio can be used as a molecular marker for early selection during proliferation phase of Brazilian pine ECs with high embryogenic potential. However, selected embryogenesis regulating genes (AB1, SERR-1, and WOX) did not show any association with the embryogenic potential in the Ecs tested.

Next, we focused on the cytochrome P450s that are involved in a vast array of reactions of many different metabolic pathways. Several triazole-containing chemical compounds have previously been shown act as efficient inhibitors of cytochrome P450 monoxygenases. A chemical library of triazole derivatives was to find chemicals which have the effect of promoting AR formation were screened. Consequently, five compounds effectively promoted AR formation.

Finally, we investigated how these chemicals affected the growth of *Arabidopsis thaliana*. *Arabidopsis* seedlings were grown on agar medium containing 1 μl selected chemicals. One of the selected chemicals, MA65 increased the number of roots in wild-type *Arabidopsis* seedlings and this phenotype was similar to a mutant supernoord [2]. The *SUR2* gene encodes the cytochrome P450 CYP83B1, a modulator of auxin homeostasis. The amounts of endogenous IAA in 14-d-old *Arabidopsis* grown in the presence of 1 mM MA65 were analyzed. The IAA content was increased two-fold in the presence of MA65 as compared with untreated Arabidopsis. In addition, 1.0 cm explants of Arabidopsis stems were incubated for 7 d on MS medium containing 1 mMMA65. Stimulation of an AR formation was observed as compared to untreated samples. Taken together, MA65 may increase endogenous IAA level in a plant cell and promotes an AR formation.

Acknowledgements: We thank Dr Tadao Asami and Dr Hitoshi Sakakibara for technical help.

21 days of culture the PS explants were collected and frozen in liquid nitrogen. RNA was extracted from shoot bud samples at day 0 and from PS explants after 7 days of culture. cDNA was then subjected to microarray analysis using an oligo-based microarray developed by the Arborea project that contains 32,000 probes. Microarray analysis lead to identification of a number of genes that was up-regulated in each genotype (1-45 fold) in response to day 7 of culture on SE induction medium. Absolute quantification qPCR of the four most up-regulated genes in each genotype confirmed the microarray results, although the magnitude of up-regulation determined by qPCR tended to be greater than that predicted by microarray analysis. In order to provide a more detailed perspective into the dynamics of gene expression, qPCR analysis of these eight genes was expanded to include 3, 15 and 21 days samples. This revealed that while differences in the magnitude of up-regulation for most of these genes differed, the overall trend in expression dynamics were very similar for both genotypes. The one exception was a gene of unknown function, which was rapidly induced in the responsive genotype, reaching a maximum at day 3 followed by progressive reduction over the remaining 18 days. In contrast, expression of this gene remained very low in the non-responsive genotype throughout the entire culture period. The expression level for three other genes peaked between 7-15 days, followed by a reduction at 21 days in both genotypes, whereas the remaining two genes showed a progressive increase up to the last day in culture in both genotypes. This project also included analysis of nine candidate reference genes, which demonstrated that expression of five were highly stable (±<±20% CV).

Effect of inorganic nitrogen concentration in co-culture and regeneration media on Agrobacterium tumefaciens growth and on the regenerative capacity of transformed Pinus radiata embryonal mass Regis Le-Feuvre 1, Claudia Triviño 2, Ana María Sabja 3, Krystyna Klimaszewska 1 1Genomica Forestal SA, CBT Universidad de Concepción, Concepción, Chile; 2Genfor S.A., Fundación Chile, sucursal Valdivia, Valdivia, Chile; 3Natural Resources Canada, Canadian Forest Service, Laurentian Forestry Centre, 1055 du P.E.S., Quebec, QC G1V 4C7, Canada E-mail: lefeuvre@gfsachile.cl

BMC Proceedings 2011, 5(Suppl 7):P141

The Genetic Engineering program at Genomica Forestal SA, Chile (GFSA) has a goal of generating stably transformed radiata pine for in planta evaluation of candidate genes. Regeneration of transgenic plants depends mainly on two factors: regeneration ability of transformed cells and stable transgene integration and expression. In several conifer species, including radiata pine, transgenics have been regenerated through cocultivation of Agrobacterium tumefaciens with embryogenic cells [1-3]. However, in our first experiments using MSG [4] culture medium we found that radiata pine embryonal masses did not recover easily after co-cultivation and that there was an excessive overgrowth of bacterial cells in spite of using bacteriostatics in the medium. This impediment prompted our study on testing other culture medium formulations, routinely used in conifer somatic embryogenesis, on the growth of A. tumefaciens GV3101. The tested media were: MSG, DCR [5]; and modified Litvay [6] MLV. Of the three media MSG supported significantly higher bacterial growth than the other two media. One of the major differences in the composition of these media is inorganic nitrogen concentration (NH\textsubscript{4}NO\textsubscript{3} and KNO\textsubscript{3}). Compared with MLV and DCR, MSG has the lowest concentration of inorganic nitrogen (100 mg/l) compared with 340 in DCR and 950 mg/l in MLV) provided in the sole form of KNO\textsubscript{3}. Based on the work of others, we concluded that low nitrate concentration in MSG medium promoted A. tumefaciens growth and this had a deleterious influence on the viability of radiata pine cells during co-cultivation, and also rendered eradication of bacterial cells difficult. Comparison of growth of radiata pine embryonal mass on the three media did not show statistically significant differences. A strategy for producing transgenic radiata pine for in planta transgene expression and stability study will be presented.

BMC Proceedings 2011, 5(Suppl 7):P143

Background: Cytokinins (CKs) are a group of phytohormones which probably regulate the growth, development, and metabolism of all plants. The aromatic CK benzyladenine (BA) has been widely applied in in vitro culture for inducing shoot organogenesis. Our study of endogenous cytokinin profiles during the caulogenic process based on mature cotyledons of stone pine (Pinus pinea L.) showed a novel metabolic pathway of aromatic cytokinins based on modification of purine skeleton.

Methods: Three-year-old mature seeds from two half-sibling selected families and open-pollinated trees of P. pinea were used [1] and the samples were collected following the Alonso et al.[2] procedure. Extraction and purification of cytokinins was based on the method described by Novák et al. [3], including modifications published later [4]. The samples were purified using a combination of a cation (SCX-cartridge) and anion (DEAE-Phadebas/C18-cartridge) exchangers. Combination of high performance liquid chromatography (HPLC) with quadrupole-time of flight mass spectrometry (QqTOF) was used for accurate and sensitive identification and quantification of cytokinins.

Results and discussion: Cortizo et al. [5] published the dynamics of BA uptake and metabolism in P. pinea cotyledons excised from embryos precultured for 2 and 4 days and cultured in vitro in modified Le Poivre media with 4.4 μM BA. In our experiment, we used 44.4 μM concentration of BA and samples were collected at different periods (0; 1; 2; 6; 16; 24 h and 2; 4; 6 d). Using high-resolution MS, the naturally-occurring BA metabolites as well as new BA forms were identified. In comparison with previously published profiles of the BA metabolite pool [3,6], the ribosyl and glycosyl forms were quantified as the most abundant metabolites. Moreover the biological activity of identified BA and its derivate was compared in various CK bioassays. The results indicate that BA uptake during the caulogenic process may be possible to regulate not only by known cytokinin pathways but also by cytokinin metabolites as well as by BA itself. Meta-analysis of cytokinin profiles give us the possibility to use cytokinin pathways as a control mechanism of BA uptake from the bud induction medium during adventitious caloegenesis in cotyledons of P. pinea. Our results help to understand the processes associated with embryo germination in plant tissue culture.

References
axillary shoots and an average of 4.3 to 5.8 shoots per explant. The WVS media proved better and presented the highest survival rate (86.0%) and highest elongation percentage (85.2%) (Figure 1). The balance of salts in WVS and W3 culture media favored an optimal development of in vitro cultures of Pinus taeda due to its lower concentration of N in comparison with MS medium and to higher concentrations of thiamine and inositol, which are growth promoters. Elongated shoots were subdivided into segments, increasing the multiplication rate to 3 segments per shoot. The majority of BAP treatments did not promote better multiplication when compared to control. However, the alternate use of 0.12 μM BAP added to WVS culture medium during initial culture and a BAP-free medium during the 1st subculture can increase the multiplication rate. The estimated production was 1024 shoots from 100 explants, in seven months of cultivation. The best rooting percentage (37.5%) was obtained in shoots treated with 2.69 μM NAA and 0.44 μM BAP for 9 days in culture medium composed of water and agar without liquid phase, followed by transfer to growth regulator-free GDm/2 medium. The double-layer medium did not increase the rooting percentage. This result was higher than that found in Pinus virginiana, when the same combination of plant growth regulators was used [13]. The roots originated directly and indirectly from the stem with callus formation. After 90 days of acclimatization, the survival rate was 90% and an average of 4.6 roots per plant was obtained (Figure 2). This result was better than that obtained in other study with Pinus taeda that reported 38% of necrosis five weeks after transplantation [14]. Micropropagation of Pinus taeda from axillary buds and juvenile material is feasible, but requires further studies to optimize the rooting stage.

Figure 2(abstract P144) Micropropagated plants of Pinus taeda, 60 days after transplanted and acclimated. Bar. 5 cm.
Background: In Brazil, especially in the Southern region, stresses caused by cold and eventual frost are those that exert the most negative effect on the productivity of Eucalyptus spp. The genetic transformation techniques may contribute to forestry improvement programs in order to obtain genotypes expressing new interesting characteristics. They allow shortening the long breeding cycles and avoiding manipulation of adult trees. Their efficiency depends on establishment of regeneration procedures that allow the development of shoots from the transformed tissues.

E. benthamii x E. dunnii hybrids have shown superiority to their parents concerning growth and frost tolerance [1], but no information about their in vitro regeneration has been reported in the literature. The objective of this study was to evaluate the effect of some factors of culture medium on indirect organogenesis and shoot multiplication of an E. benthamii x E. dunnii clone.

Methods: In vitro established shoots provided by EMBRAPA-Florestas (Colombo, PR, Brazil), were used as explant source. Cultures were maintained under white fluorescent tubes providing a photon flux density (PFD) of approximately 20 μmol m$^{-2}$ s$^{-1}$, a 16-h photoperiod and a temperature of 25±2 °C. The cultures were performed in glass flasks containing 25 mL MS [2] medium supplemented with 1.11μM BA and sealed with rigid polypropylene caps. For the indirect organogenesis, leaves were excised from shoots at the petiole base, split into two halves and inoculated in the selected culture media. The cultures were done in Petri dishes kept in a growth chamber in the dark throughout the experiment.

The statistical design was performed in a factorial scheme (2:2:2) and a comparison was done between two culture media (MS-N/2, with half concentration of potassium and ammonium nitrates, and JADS [3] with 0.1 μM NAA, with and without PVP-40 (250 mg L$^{-1}$) and two TDZ concentrations (0.1 and 0.5 μM).

After 70 days, the percentages of explants forming callus, oxidized explants, explants producing anthocyanin, explants forming buds and shoots, and the number of shoots per explant were evaluated. For the multiplication test, the statistical design was performed in a factorial scheme (3:2) with three culture media (MS, WPM [4] and JADS, with 1.11μM BA) and two subcultures (28 and 56 days after the initial culture period). The analyzed variables for each subculture were: percentage of oxidation, of explants showing chlorosis, fresh weight and number of shoots.

Results and discussion: Regarding the oxidation, the higher rates (100%) were observed on JADS medium in presence or absence of PVP-40 and on MS-N/2 medium (68.3%) in presence of PVP-40. However, the JADS medium showed the highest percentage of callus formation (83.3%). In MS-N/2 medium the highest percentage of callus formation (55%) was found in the presence of PVP-40 and 0.5μM TDZ. Similar results were observed [5] with E. saligna leaf explants cultured on MS-N/2 medium supplemented with 1.11μM NAA and 1 μM TDZ. Anthocyanin was only observed in explants cultured on MS-N/2 medium without PVP and containing 0.5μM TDZ. The lowest percentage of explants presenting anthocyanin was observed on MS-N/2 with PVP-40 that gave the best result for organogenesis (8.3%).

For the multiplication experiment, the variance analysis did not reveal significant interaction between the factors. During the first subculture MS medium with 1.11μM BA promoted the highest number of shoots/explant (9.2). The explants cultured on MS medium showed the highest fresh weight (0.384g) and highest percentage of chlorotic explants (88%). The percentage of oxidized explants was the same on JADS and MS media (40%). In a study on E. urophylla x E. globulus shoot multiplication [6], an increase of oxidation was also observed on JADS medium in comparison with MS medium. With regard to the second subculture, the number of shoots per explant and percentage of oxidation did not differ among the treatments. The explants cultured on MS medium showed the same behavior for the chlorosis than during the first subculture and the percentage of chlorotic explants was similar to that observed in others treatments (64%). On WPM medium, the mean number of shoots/explant was the highest (9.08).

Conclusions: E. benthamii x E. dunnii hybrid has a low organogenic response to the tested combinations of growth regulators and high tendency to oxidation even when an antioxidant is present in the culture medium. However, the concentration of PVP-40 used in this study may have been low and other types of antioxidants and concentrations need to be compared. The MS medium with 1.11 μM BA promoted the highest number of shoots per explant after a 28 day culture period, and after 56 days, there were no differences among the treatments.

**Background:** Several factors may affect the genetic transformation efficiency of woody species. One factor is the use of an efficient selective agent that inhibits the development of non-transformed cells and just allows the development of transformed tissues. The most used selection agent is the neomycin phosphotransferase II (*NPTII*) gene, which confers resistance to aminoglycoside antibiotics kanamycin, neomycin and G-418 [1].

The selective agent concentration in culture medium may have influence on shoot regeneration and high concentrations may promote adverse effects on organogenic potential [2]. The kanamycin effects in *Eucalyptus* are variable and depend on the species and genotypes [3]. The purpose of this study was to evaluate the effect of kanamycin concentration on transformation efficiency for *Eucalyptus saligna* cotyledons after co-culture with *Agrobacterium tumefaciens*.

**Methods:** The bacterial strain was EHA 105, containing a binary vector carrying the GUS gene under control of CaMV35S promoter and NPTII gene under control of the same promoter. Cotyledons from twelve days old *E. saligna* plantlets were co-cultured for 30 min in the bacterial suspension (OD₆₀₀nm = 0.5) followed by a 5 day co-culture on MS culture medium containing 2.7 μM NAA + 4.4 μM BAP in the dark. The explants were then transferred on the same medium supplemented with (1) 12.5 mg L⁻¹ kanamycin (Km) + 300 mg L⁻¹ Augmentin (Aug); (2) 25 mg L⁻¹ Km+ 300 mg L⁻¹ Aug and (3) 50 mg L⁻¹ Km+ 300 mg L⁻¹ Aug. The explants were subcultured in the same culture medium every 15 days and, after 60 days, the percentage of oxidation, callus and shoot formation, and shoot number per explant were evaluated. DNA was extracted from fresh young leaves and processed according to the specific protocol [4]. The presence of GUS gene in the putative transformed plants was confirmed by PCR 10 months after inoculation. Gus expression was studied by histochemical test for β-glucuronidase, three and 120 days after inoculation.

**Results:** With regard to the percentage of oxidation, percentage of callus formation and percentage of shoot formation, there was no significant difference among the three treatments. The percentages of explants...
regenerating shoots were 24, 15.9 and 14.6 respectively for the three Km concentrations, after 60 days of co-culture period. The lower concentration of kanamycin (12.5 mg L\(^{-1}\)) showed best results for shoot regeneration (24%) and number of shoots per explant (3.9) and these results were statistically different of those obtained with other treatments. Three gus positive events were regenerated from explants cultured on medium containing 12.5 mg L\(^{-1}\).Km and the transformation efficiency was 0.0075%.

**Conclusion:** The concentration of 12.5 mg L\(^{-1}\).Kmallowed the shoot induction from genetic transformed tissues and was considered satisfactory for selection of transformed tissues. The information presented in this study constitutes the basis for optimization of the genetic transformation of other *E. saligna* genotypes.

**Induction and repetitive embryogenesis of Ocotea porosa**

**Marguerite Quoirin**\(^1\), Luciana Pelegini\(^2\), Luciana Ribas\(^3\)

\(^1\)Universidade Federal do Paraná, Brazil; \(^2\)UFPRm Brazil; \(^3\)E-mail: mquoirin@ufpr.br

**BMC Proceedings 2011, 5(Suppl 7):P148**

**Introduction:** *Ocotea porosa* (Liberato Barroso) known as “imbuia” belongs to the Lauraceae family and is native to the Mixed Ombrophilous Forest (Araucaria Forest) where it was heavily exploited due to the high quality and worldwide value of its hardwood that is exported in large quantities for luxury furnishing manufactures [1]. The sexual propagation of *O. porosa* at its natural occurrence area is difficult, due to the strong testenuary dormancy and its irregular germination. Moreover, the seed viability is short by virtue of being a recalcitrant species, showing high level of humidity [1]. Another limiting factor for its vegetative propagation is the low response of cuttings to the induction of adventitious roots (4%) [2]. The aim of this study was to establish repetitive cycles of secondary somatic embryogenesis from *O. porosa* embryonic axes.

**Material and methods:** Zygotic embryonic axes from immature seeds were used as explants. The seed disinfection was performed in a laminar flow chamber, through immersion in ethanol 70% (v/v) for 5 min, followed by 20 min in NaOCl 4% (v/v) supplemented with 0.1% of Tween\(^\circ\) 20. After that, the seeds were rinsed five times with sterile water. The WPM [3] culture medium was used in all stages. Embryonic axes were inoculated on culture medium supplemented with sucrose (20 g L\(^{-1}\)), activated charcoal (1.5 g L\(^{-1}\)), agar Vetec\(^\circ\) (4 g L\(^{-1}\)) and2,4-D (22.62 μM) combined or not with hydrolized casein or glutamine for 30 days. The maturation of embryos developed to cordiform stages. However, in the present conditions of maturation, the percentage of embryos developing to cordiform, torpedo and cotyledonal ontogenetic stages was low, revealing an asynchronous development. In both treatments (3.5 and 7% PEG) as well as in the control, the first response was the formation of pro-embryogenic masses in 100% of calli. The percentage of calli with somatic embryos was 6.3% and the percentage of 6.5% [4]. On the culture medium containing 200 μM 2,4-D, the percentage of calli with somatic embryos was 6.3% and the formation of one globular embryo was visible. When 200 μM 2,4-D was combined with 1 g L\(^{-1}\) hydrogen casein this percentage was 6.3% and two globular somatic embryos were developed per callus. In repetitive embryogenesis from initial to late stages. However, in the present conditions of maturation, the percentage of embryos developing to cordiform, torpedo and cotyledonal stages was low, revealing an asynchronous development. In both treatments (3.5 and 7% PEG), an average of 32.7 and 27 new globular embryos were formed per explant. During maturation phase, the somatic embryos develop from initial to late stages. However, in the present conditions of maturation, the percentage of embryos developing to cordiform, torpedo and cotyledonal stages was low, revealing an asynchronous development. In both treatments (3.5 and 7% PEG), an average of 32.7 and 27 new globular embryos were formed per explant. When PEG concentration in culture medium was 7%, the formation of new globular embryos decreased (12.7), but the development of cordiform (1.5), torpedo (2) and cotyledonal embryos (2) was observed.

**BMC Proceedings 2011, 5(Suppl 7):P149**

**Background:** Commercial micropropagation of teak (*Tectona grandis*) has been achieved for a number of years in countries such as Thailand, India and Malaysia. This has led to the availability of elite genotypes for large scale plantation production. Teak has been shown to develop arbuscular mycorrhiza (AM) fungal associations [1], and this has been attributed to increasing productivity [2]. It is likely that the establishment of mycorrhiza, through the introduction of Glomusspecies, on the roots of micropropagated plantlets will improve the productivity of selected
clones. Established hyphal networks can speed up plant colonization [3] and in the long term may also increase carbon storage through glomalin production [4]. Our research is pursuing the development of a mycorrhization protocol for micropropagated teak at the acclimatization stage.

**Methods:** Shoots of two clones of teak were multiplied on media containing Murashige and Skoog [5] nutrients and organics, 30 gL⁻¹ sucrose, 0.5 μM benzyl amino purine, 0.5 μM kinetin, 2.5 gL⁻¹ agar, 2.5 gL⁻¹ gelrite and a pH of 5.8. Individual shoots were subsequently exposed to a medium containing ¼ strength M&S macronutrients, full strength M&S micronutrients, 60 mM sucrose, 2.5 gL⁻¹ of agar and 2.5 gL⁻¹ of gelrite [6], and a range of indole butyric acid (IBA) concentrations (0-160 μM) for varying lengths of time (4-28 days) to produce roots in vitro. Rooted plantlets were transferred to three pasteurised soil types (1sand:1perlite; 1sand:1peat; and 1sand:1perlite:1peat) under the following conditions: they were maintained under mist (covered 75-95% humidity) for 5 weeks followed by hardening through gradual reduction in humidity (50-65%) on greenhouse benches for a further 5 weeks. Plant survival, height and root area were measured. Two clones of *T.grandis* were exposed to different inoculum sources and various inoculation techniques during the acclimatization period. Unprocessed commercial AM inoculum 100 g kg⁻¹ from a legume/grass pot culture (chopped mycorrhizal roots and soil) or processed commercial AM inoculum 10 g kg⁻¹ were both mixed with pasteurised inert soil (1sand:1perlite) and watered to field capacity with ½ strength sorghum nutrient solution [7]. When the processed inoculum was used, roots were also dipped into the inoculum powder before being planted. All plants were acclimatised under high humidity as above and periodically fertilized with ½ strength sorghum nutrient solution. Plantlet height, root area and mycorrhizal development were assessed at 10 and 20 weeks and means compared using analysis of variance and Tukey’s multiple range test.

**Results and discussion:** Optimum root production, (8.6 ± 0.7 roots per shoot) and tallest plants were obtained from shoots exposed to 80 μM IBA for 8 days. However, shoots from higher IBA (160 μM) concentrations had lower survival rates but there was no effect on the growth of the plantlets that survived. Soil type used for acclimatisation did not affect plant height and root area measurements. This allowed the acclimatisation to be conducted in a soil type that is considered most appropriate for mycorrhization development [7]. At 10 weeks, 100% of inoculated plantlets had survived. Mycorrhizal inoculation using unprocessed AM commercial inoculum increased root area (609.9 ± 46.2 mm²; Fig 1 A & B), a similar result to that of [8] for micropropagated grapes. This was achieved, however, for one clone only. Teak root infection was also achieved using the high concentration of the unprocessed AM commercial inoculum 20 weeks after inoculation. Control plants were not infected. A preliminary comparison of the inocula used showed that early evidence of mycorrhization can also be achieved using soil pot culture (Figure 2) which agrees with [3].

**Conclusions:** *T. grandis* can be inoculated and ex vitro mycorrhization achieved during the acclimatization phase of micropropagation. The time required for the mycorrhization appears to be dependent upon inoculum source, and perhaps other factors that are currently being investigated such as inoculum concentration and substrate phosphorus contents. In addition, early results indicate that successful mycorrhization may vary between host genotypes. The availability of clonal, mycorrhizal teak may lead to greater plantation sustainability through more appropriate fertilizer regimes and greater carbon storage.

Embryogenic potential and expression of embryogenesis-related genes in conifers are affected by treatment with a histone deacetylase inhibitor

Daniel Uddenberg, Silvia Valladares, Malin Abrahamsson, Jens F Sundström, Annika Sundás-Larsson, Sara von Arnold, Uppsala Biocenter, Department of Plant Biology and Forest Genetics, Swedish University of Agricultural Sciences (SLU), Uppsala, Box 7080, SE-750 07, Sweden; 2Evolutionary Biology Center, Physiological Botany, Uppsala University, Uppsala, SE-752 36, Sweden; 3Department of Plant Physiology, Instituto de Investigaciones Agrobiologicas de Galicia (CSIC), Santiago de Compostela, Apartado 122, 15780, Spain; E-mail: daniel.uddenberg@slu.se

BMC Proceedings 2011, 5(Suppl 7):P151

Background: Somatic embryogenesis is a useful method to propagate conifers vegetatively. In many coniferous species embryogenic cultures can be established from zygotic embryos, while the embryogenic potential decreases during germination. Embryo formation is thought to require a signal that induces a somatic cell to dedifferentiate and gain embryogenic potential as well as the expression of an appropriate cellular environment for the response of the inductive signal. In *Arabidopsis thaliana* (*Arabidopsis*) LEAFY COTYLEDON (LEC) genes are expressed during the embryonic stage but must be repressed to allow germination [1]. Treatment with the histone deacetylase inhibitor trichostatin A (TSA) causes de-repression of LEC genes. In addition, ectopic post-embryonic expression of LEC is sufficient to induce differentiation of embryo-like structures from vegetative cells [2]. ABSCISIC ACID3 (ABI3) and its maize (*Zea mays*) orthologue VIVIPAROUS1 (VP1) act together with the LEC genes
to promote embryo maturation [3]. Knowledge about the molecular mechanisms underlying embryogenic competence in conifers is largely uncharacterized, although this is the foundation for propagation of conifers through somatic embryos. However, we have recently shown that TSA-treatment affects both the embryogenic potential and the expression of embryogenesis-related genes in Norway spruce [4].

Materials and methods: Conifer sequences of LEC1-type HAP3 genes and ABI3/VP1 homologues were retrieved from public databases and isolated in Norway spruce (Picea abies) and Scots Pine (Pinus sylvestris). Phylogenetic analyses were done on nucleotide alignments of conserved domains made using Bayesian inference (MrBayes) and maximum parsimony (PAUP*). Embryogenic cell lines 06.28.05 of Norway spruce and 12:12 of Scots pine were used in this study. To analyze the effect of TSA (Sigma-Aldrich) during maturation and germination of somatic embryos of Norway spruce, the growth media were supplemented with 10μM TSA. Expression levels of the conifer HAP3A and VP1 genes were assessed using quantitative real-time PCR.

Results and discussion: We isolated two conifer LEC1-type HAP3 genes, HAP3A and HAP3B, from Norway spruce and Scots pine. A comparative phylogenetic analysis of plant HAP3 genes suggests that HAP3A and HAP3B are paralogous genes originating from a duplication event in the conifer lineage. The angiosperm ABI3/VP1 genes belong to the plant specific B3 gene family and phylogenetic relationship position the conifer homologs closest to ABI3 and VP1. The expression of HAP3A is high during early embryo development but decreases during late embryogenesis, while the expression of VP1 is initially low and increases during late embryogenesis, in both Norway spruce and Scots pine. The expression levels for both genes are similar during somatic and zygotic embryogenesis. When embryogenic cultures of Norway spruce were exposed to TSA during embryo maturation, maturation was arrested and the expression levels of PatHAP3A and PatVP1 were maintained. Furthermore, when germinating somatic embryos of Norway spruce were treated with TSA, the germination progression was partially inhibited and the embryonic potential was maintained at a similar level as embryos before germination.

Conclusions: Taken together, our results suggest that important regulators of embryogenesis are conserved between angiosperms and gymnosperms, and, assuming that TSA affects histone acetylation in conifers, our results indicate a connection between between chromatin structure and expression of embryogenesis-related genes in conifers.

BMC Proceedings 2011, 5(Suppl 7):P152

Background: The genus Populus has certain important features, such as a relatively small nuclear genome, it can be easily regenerated easily in vitro and genetically transformed by Agrobacterium vector system, which make it ideal for gene transfer and molecular genetic studies in forest trees [1]. Insect-tolerant poplars have been obtained using several types of insecticidal genes coding for Bacillus thuringiensis-toxins. Regenerated plants with insect-resistance were obtained in different studies. Agrobacterium-mediated transformation has been the favored method for the introduction of foreign genes into plants. The effectiveness of insect-resistance in transgenic plants is related to the site effects of gene transfer (site of gene insertion, copy number, gene silencing etc.). Moreover, intransgenic plants, transgene copy number can greatly affect the expression level and genetic stability of the target gene, making estimation of transgene copy numbers an important area of genetically modified plant research [2]. Thus molecular biological analysis of transgenic plants, like real time PCR, widely used to detect and quantify DNA and cDNA [3], could represent an useful tool to investigate the genetic stability of transgenic forest trees having a long life cycles well as for determining copy number in transformed plants.

Material and methods: The present study was undertaken to investigate Populus alba and P. tremula x P. tremuloides transgenic lines, obtained via Agrobacterium-mediated transformation, carrying cry1Ab and nptII genes in the T-DNA region. The plants were vegetatively propagated in growth chambers over 2 years. Ten individuals from each clone were planted in containers with "forest soil", and grown in a climate chamber. Extraction of genomic DNA and RNA from leaves was performed for PCR and Real Time PCR (RT-PCR) analysis to estimate the transgene copy number [4] as well as expression of the inserted gene [5] in transgenic poplar, respectively.

Results and discussion: All lines contained one copy of cry gene and two of them showed that the copy number was different for the cry1Ab and nptII genes, suggesting rearrangements or multiple but incomplete copies of the transferred DNA (Figure 1). The copy number was concordant among the 3 individuals of each lines analysed and with those determined from the same transgenic lines kept in micropropagation for 2 years.

Figure 1(abstract P152) Copy number values estimated by real-time PCR. Data are expressed as mean ± 95% confidence limit.

Figure 2(abstract P152) Relative expression obtained through qRT-PCR for the transgenes cry1Ab and nptII in transgenic Populus lines. The data are shown relative to the endogenous actin gene. Boxes: interquartile range, or the middle 50% of observations; dotted line: median gene expression, whiskers: minimum and maximum observations. Data are expressed as mean ± 95% confidence limit after 10000 permutations and have a p = 0.000 – 0.002.
The transcript levels from both genes were determined in 3 individuals for each line growing in climatic chambers. High levels of mRNA expression were detected with respect to the stable endogenous actin gene for both transgenic lines (Figure 2). Comparing the transcript level of inserted genes among lines, a significant low level of nptII gene ($p = 0.005$) in the line carrying 3 copies was observed. Preliminary results indicate a differential expression of endogenous genes among transgenic lines and towards their isogenic form.

**Conclusions:** The evaluation of the copy number of the inserted genes has indicated their stability after 2 years of micropropagation. The lower expression level of the nptII inserted gene in one line could suggest that factors like position effects or DNA rearrangements lead to differential expression.

The screening of the transcriptomic variations in transgenic plants carrying the cry gene and the comparison with position effects or DNA rearrangements is in course. The final aim is to unravel possible pleiotropic transcriptomic effects following cry gene expression in P. alba and P. tremula x P. tremuloides transgenic lines.

**BMC Proceedings 2011, 5(Suppl 7):P153**

**Background:** Despite its importance as a widely-planted crop tree, eucalypt species and hybrids are relatively difficult to micropropagate, culture and genetically transform in vitro. Compared to other plant species, few non-commercial laboratories are proficient at *Eucalyptus* tissue culture and transformation. We have undertaken to establish and transform several eucalypt clones in the laboratory. Our main aims include the identification of clones amenable to culturing and transformation, and the development of robust and transferable micropropagation, organogenesis and transformation protocols to enable routine production of transgenic eucalypts for public sector research. Efficient transformation protocols are essential to take full value of the eucalypt genome for functional genomics, ecophysiology, and biotechnology.

**Methods:** Five different clones of *E. grandis* (including the clone of which the genome was recently sequenced – Brass1) as well as a single *E. grandis* x *urophylla* hybrid were established in the laboratory. Light intensity was studied as a means to reduce browning and promote callus growth and shoot regeneration. Gibberellic acid (GA3) concentrations in the micropropagation medium (Murashige and Skoog’s (MS) basal medium containing 0.05 mg/L benzylaminopurine – BAP) were studied to help produce long internodes to aid transformation in vitro. To mitigate phenolic production we used several different antioxidants including ascorbic acid, PVP and PVPP. Shoot regeneration rates were studied by testing a concentration range of cytokinin (zeatin, benzyl aminopurine – BAP and thidiazuron – TDZ). We tested different *Agrobacterium* transformation protocol enhancements including the use of acetosyringone and two different co-cultivation techniques (whole explant immersion versus pipetting of *Agrobacterium* suspension onto cut leaf edges). We also tested the suitability of kanamycin and hygromycin as selectable markers during transformation.

**Results and discussion:** Light conditions during shoot regeneration were critical to the rate of organ regeneration, with more than 50% of explants producing shoots in the presence of reduced or indirect light, compared to approximately 30% incubated under normal light conditions. In addition, shoot differentiation occurred earlier (10-14% at 40 days) under reduced or indirect light compared to normal light (1%; Fig. 1).

We have also begun to test the use of muslin screens to identify the best level of light exposure. The optimal level of GA3 in the micropropagation medium for the production of sturdy elongated internodes was found to be 0.05 mg/L. It was also apparent that the recovery of micropropagated plantlets on medium without GA3 for 21 days prior to internode harvesting improved plant health and produced better quality stem sections for transformation. Ascorbic acid, used as a means of reduction of phenolic browning, proved to be ineffective when used alone, even though it produced no adverse effects on callus health. By comparing several shoot induction media (SIM) for shoot regeneration from stem and leaf explants of the *E. grandis* x *urophylla* containing different cytokinin combinations, we found that the highest rates of shoot regeneration (11.8%) occurred when using stem explants incubated on SIM containing 1 mg/L NAA (nicotinamide) and 10 mg/L zeatin. Of the five tested *E. grandis* clones, we found that the highest rates of shoot regeneration (52%) were found from leaf explants of clone p207 in the presence of SIM containing 3 μM TDZ and 0.1 μM NAA. Neither the use of two different acetosyringone concentrations (250 and 750 μM) during co-cultivation, nor either of the two co-cultivation techniques (immersion and pipetting) had a significant effect on transient gene expression measured shortly after cocultivation. Testing of different kanamycin and hygromycin concentrations (”kill curve”), revealed that 30 mg/L kanamycin or 5 mg/L hygromycin can be used for the selection of putative transgenics after transformation (Fig. 2).

**Conclusions:** There is significant variability in the performance and response of different clones of *Eucalyptus* during micropropagation, organogenesis and transformation. Testing of multiple *Eucalyptus* clones confirmed that the genus is relatively unwieldy in tissue culture compared, for example, to *Populus*. We found that explant type (stem vs leaf for example), and quality (age, general health, absence callus browning) as well as finely-tuned phytohormone concentrations, will play critical roles in enhancing the probability of the successful generation of stable transgenic lines.

**Figure 1** (abstract P153): Percentage of shoot regeneration from co-cultivated leaf explants of a *E. grandis* x *urophylla* clone under different light conditions.

Functional markers development and genetic diversity analysis in Eucalyptus globulus with emphasis in wood quality candidate genes

Cintia Acuña, Pamela Villalba, Martin García, Esteban Hopp, Susana Marcuccio Poletti Instituto de Biotecnología, CICVYA, INTA Castelar, CC 25, Castelar (B1712WAA), Argentina

E-mail: cacuina@cia.inta.gov.ar

BMC Proceedings 2011, 5(Suppl 7) P154

Background: Eucalyptus globulus is the most planted hardwood species for pulpwood in temperate regions. Genomic researches in Eucalyptus have increased the information available in DNA sequences public databases and several structural and regulatory genes involved in the cellulose and lignin pathways are known. Functional genetic markers, while frequent in crop, are still scarce in forest species. Hence the detection and validation of SSRs in interesting genes to be used in future projects of marker-assisted breeding are needed.

The present study aimed the development of novel functional markers (SSRs) in ESTs and wood quality candidate genes (CG) from Eucalyptus globulus, and analyzes their potential for genetic diversity and individual identification studies.

We report the design of SSR primers flanking simple sequence repeats in ESTs and CG, the validation of a subset of randomly selected EST-SSRs using eight E. globulus genotypes and the screening of a sample of 60 trees with the polymorphic SSRs. Also, SSRs cross-transferability was tested in seven Eucalyptus species coming from three sections: E. grandis, E. saligna (section Latuangularia); E. globulus, E. dunnii, E. viminalis (section Maidenaria); and E. camaldulensis, E. tereticornis (section Exsertaria).

Material and methods: Plant material: A total of 60 trees, each from a different OP family of E. globulus, were analyzed for their variability. These sixty trees represented major geographical races of the species natural distribution that were grown in a field trial in the Province of Buenos Aires, Argentina, between 1995 and 1997. For validation analyses one individual of each race (except Furneaux) was included. A total of 47 individuals from seven species (including E. globulus) of the genus were sampled for the transferability analyses.

Methods: Novel microsatellites were identified mainly by two different methods. -SSR detection from non redundant ESTs of E. globulus from GenBank: Annotations of these SSR-ESTs were based on the Gene Ontology (GO) (http://www.geneontology.org/) using Blast2GO (http://www.blast2go.org/) [1]. For validation and diversity analyses, amplification products were silver-stained or analyzed through an ABI3100 Genetic Analyzers (Applied Biosystems, USA) with fluorescent dyes respectively. SSR statistics for determining number and frequency of alleles, effective number of alleles (N_e), observed heterozygosity (H_o) and unbiased expected heterozygosity estimates (U_H_e), fixation index (F_I) and probability of identity (PI) were determined with the GenAlEx 6.4 program [2]. Tests for Hardy-Weinberg equilibrium were conducted using GENEPOP 4.0.10 [3]. Null allele frequencies were estimated with INEST software (Inbreeding/Null allele estimation) [4], using and Individual Inbreeding Model (IIM) with 10,000 iterations. Structure analysis was explored through UPGMA and DAS (Shared allele distance) indices as well as Structure [5] software.

Results: From 12,690 updated E. globulus EST database published in National Center for Biotechnology Information a total of 4,924 non-redundant sequences were identified. From these ones, 952 unigenes (19.3%) contained 1,140 SSRs. A new set of 979 primers was designed. Redundant sequences were identified. From these ones, 952 unigenes (19.3%) contained 1,140 SSRs. A new set of 979 primers was designed. Sixty five percent out of a total of 85 SSR (56 EST-SSRs and 29 SSR containing GC) detected in this study were validated for actual PCR amplification of tree DNA samples in eight genotypes of E. globulus. From this assessment a total of 17 polymorphic EST-SSRs and 12 polymorphic CG-SSRs markers were obtained. These ones were selected for further analyses, so as to accurately estimate genetic information content in a larger sample of 60 non related trees represented major geographical races of the species natural distribution. PIC, H_o and U_H_e values varied over a wide range from around 0.02 to 0.9, whereas the allele number ranged from 2 to 16, with and average of 7.55. A set of 49 loci (37 validated EST-SSRs (polymorphic and monomorphic) and 12 polymorphic CG-SSRs) were also tested for cross-transferability to other six Eucalyptus species (E. grandis, E. saligna, E. dunnii, E. viminalis, E. camaldulensis, E. tereticornis). A total of 33 out of the 49 validated markers in E. globulus amplified in the six other species and six markers amplified in at least other five.

Finally, the analyses of polymorphism and transferability of functional markers, enabled the selection of a set of 13 (7 EST-SSRs and 6 GC-SSRs) highly informative and transferable to six other species of Eucalyptus.

Conclusions: The set of highly informative markers developed here will have potential use in studies of genetic diversity, taxonomy, gene mapping and will help the improvement of Eucalyptus through the assisted selection.
Thirty percent of EST-SSRs (17 from 56) are expected to be polymorphic in *E. globulus* and 25% (14 polymorphic from 56) are expected also to be transferable to other six species (*E. grandis*, *E. saligna*, *E. dunnii*, *E. viminalis*, *E. camaldulensis* and *E. tereticornis*). Under these proportions, potentially more than 200 new EST-SSRs described here may contribute to the verification of synteny and collinearity between different *E. globulus* maps, and would allow the validation of gene and QTL positions in multiple pedigrees in the botanical sections *Maidenaria*, *Exsertaria*, and *Latoangulatae*, to which most of the commercially planted eucalypt species belong.

BMC Proceedings 2011, 5(Suppl 7):P155

Background: Eucalyptus spp. is a genus widely planted in many tropical and subtropical regions of the world as a major source in the production of pulp and paper. Aiming to meet the demand required by the world market papermaker, with the need for greater productivity in forests, as well as higher quality of wood, reducing the amount of lignin and extractive, is that proteomics emerges as an additional tool to help accelerate progress in the selection of elite clones.

Materials and methods: In this study, using the combination of the two-dimensional gel electrophoresis (2D-PAGE) and electrospray mass spectrometry on quadrupole-time of flight (ESI-QUAD-TOF) identify differentially expressed proteins between four genotypes of eucalyptus, brothers siblings, contrasting with differences for components of wood quality. The components evaluated in this study for four xylems were: wood density, which was higher in clones X1 and X2, total lignin content, with levels higher in the X3 and X4 clones, extractive content, with higher values for the clones X2 and X4, and gross yield in pulp, which was higher in clones X1 and X3. Whereas the desirable characteristics for application in pulp and paper industry is the clone that best combines the highest density of wood and pulp yield, with lower lignin content and extractive, the X1 is the clone that best meets these criteria, the most suitable for such application, and X4 clones, considered inadequate for the same process.

Results: The profile followed by 2D gel analysis software with 3D Image Master Platinum xylem protein extracts of these clones resulted in identification of 30 spots differentially expressed, with 3 proteins in clone X1, 4 proteins in clone X2, 11 proteins in clone X3 and 12 proteins in clone X4. These differential spots were excised, subjected to tryptic digestion and processing, followed by mass spectrometry analysis. The identified proteins are involved in various biological processes, including polyphosphate biosynthetic process, catalytic activity, nucleotide-excision repair, cellular metabolic process, cell redox homeostasis, response to salt stress, response to heat, oxidation-reduction process, potassium ion transport, electron transport chain, response to wounding, superoxide metabolic process, response to water deprivation, protein phosphorylation.

It is noteworthy that the proteins involved in oxidative stress were up regulated in clone X4, followed by clones X2 and X3, and to a lesser extent in clone X1. Among the proteins differently expressed in clone X4 can highlight catalase, superoxide dismutase, annexins, heat shock protein (chaperone) and ABC transporter. Catalase is an enzyme that converts H2O2 in O2 + 2H2O, primarily by preventing the potential damage caused by changes in H2O2 homeostasis [1]. The superoxide dismutase is the first line of plant defense against reactive species of O2, O2- removing the cellular compartments where this radical is formed [2]. Annexin peroxidase may play a role as the process of oxidative stress in plants [3].

Conclusions: The proteins identified in the study involved in redox process in the plant, as well as the extractives, including polyphenols, tannins and resins, components characterized as inadequate in the pulp and paper industry, are induced as a defense response to pathogen attacks as well as to abiotic stress [1,6]. Furthermore, it has been demonstrated that oxidative stress can also induce lignification in plant tissue [7,8].Given this, we infer that the presence of proteins involved in oxidative stress in the xylem of a eucalyptus is a strong predictor of inappropriate clones in the pulp and paper industry.

Selection of candidate genes and validation study of gene expression through genetic materials in the wood quality will be known the next step in the selection of genetic markers to identify elite clones of eucalyptus for the pulp and paper production.

Oxidative stress as an indicator of lower quality eucalyptus for pulp and paper industry

Dahyana Britto1*, Carlos Pirovani1, Esteban Gonzalez2, João Silva2, Abelmom Gesteira1, Júlio Cascadéro3

1Center of Biothecnology and Genetics, Dep. of Genetics and Molecular Biology, Universidade Estadual de Santa Cruz - UESC, Ilhéus, BA, 45662-900, Brazil; 2Suzano Paper and Cellulose S.A., Mucuri, BA, 45936-000, Brazil; 3Brazilian Enterprise for Agricultural Research cassava and fruit - EMBRAPA., Cruz das Almas, BA, 44380-000, Brazil; *In memoriam

E-mail: dahyana@yahoo.com.br

BMC Proceedings 2011, 5(Suppl 7):P156

Background: Wood is the most important natural and renewable source of infinite energy, but this is not their only function, it also has great significance to the buildings and other products [1]. Eucalyptus, the genus that includes more than 500 species, is among the key forest species planted around the world to solid wood, and mainly for the pulp and paper industries. Aiming at the sustainable use of timber, supplying the
demand and meeting the requirements of the paper industry, genetic breeding programs looking for, among other agronomic traits of interest, improve the quality of wood, that is, lower lignin and extractive, and increase the density wood and pulp yield. Therefore, it is interesting to identify genetic markers that characterize the major events of xylem differentiation, as well as stress response, because it is key factors to determine some properties of wood, affecting their performance and industrial value. Thus, this study aimed to identify genes specifically involved in oxidative stress response and characterization of genes in determining the quality of the wood.

Materials and methods: To this end, we constructed a Suppression Subtractive Hybridization 3 – SSH3 using two samples of xylem. These samples were extracted from trees of a population of sib eucalyptus from a commercial plantation Suzano with contrasting characteristics to wood quality, among them, lignin content and total amount of extractive, higher for the clone X4, and basic density and cellulose yield, for the largest clone X1, the latter considered as higher for the production of pulp and paper. After identification and selection of genes of interest was the analysis of the expression for Real Time PCR with the same clones of Eucalyptus used in making the library.

Results: From the sequencing and bioinformatics analysis of the library has been possible to identify a total of 449 sequences and 90 contigs in SSH1 and SSH2, respectively. Among the unique unigenes, annotated by the program Blast2GO versao1.2.7 in SSH3 were identified proteins involved in oxidative stress response and heat shock protein, ABC transporter and glutamine synthetase. After analyzing for real-time PCR for validation of these sequences more representative, was unable to confirm the decreased expression of all genes in clone X1 compared with the X4 clone.

Conclusions: The result was expected for these clones, since the plants when in oxidative stress caused by abiotic and biotic agents, activates the defense mechanism through the expression of genes involved in stress response, as well as accumulated extractives as polyphenols, tannins and resins [2]. So, the ABC transporter, for example, between genes possibly involved in this process, carries lignin monomers to enhance the cell wall making it difficult the entry of pathogens [3,4]. The small heat shock proteins, also known as molecular chaperones, although not expressed constitutively, are abundant in plants, especially when under stress, as observed by Hamdahl and collaborators, in transgenic Arabidopsis thaliana [5]. As glutamine synthetase, this protein is involved in improving the assimilation of nitrogen by the plant [6]. Other words, in a soil poor in nitrogen, such as soil Formation Barriers/Spodosol where these clones were grown, these proteins must play important role in plant growth, once the availability of this nutrient is limiting factor growth of eucalypts [7]. In addition, this protein has an important role in maintaining the health of the plant to attack by pathogens [8]. Considering this, it was note worthy that the signaling proteins were oxidative stress Eucalyptus clone, and that the result reinforces the idea that proteins involved in oxidative stress response is related to the high concentration of extractive and lignin.

Preliminary tests in Real Time PCR with the juvenile offspring of these clones are already underway. But in order to reaffirm the presence of these genes involved in oxidative stress to the condition of poor quality for the production of pulp and paper, the expression analysis performed in the progenies of appropriate age and assessment of components involved in wood quality are needed.

Background: The cashew tree (Anacardium occidentale) is found throughout the Brazilian territory, although it is better adapted to the northeastern coast climate. This fruit crop is essential to the agroindustry of the States of Ceará, Piauí and Rio Grande do Norte, where around 95% of the production is harvested and where the whole processing of the chestnut is done. It currently represents 157 million dollars in exports of nuts. Despite its socio-economic importance it still lags behind in the adoption of breeding technologies. There is very little information about the genetics of this species and no molecular tools yet developed. In this work we developed and characterized a set of microsatellite markers for Anacardium occidentale from the construction of genomic libraries enriched for repetitive sequences.

Material and methods: The markers developed were used in studies of genetic relationships among samples of the germplasm bank, and saturation of existing genetic maps of the species. Genomic libraries enriched for microsatellites were constructed and out of the 5,472 selected clones, 540 were sequenced and analyzed for the presence of microsatellites. A total of 117 sequences containing microsatellites were selected to design PCR primers and screen the resulting markers. One hundred pairs of primers were synthesized and initially tested for amplification in agarose gel. Fourteen markers were selected and characterized by fluorescent detection in an ABI 377 sequencer based on genotyping a representative set of 35 samples derived from the germplasm collection. Genetic parameters such as observed heterozygosity (Ho), expected heterozygosity (He), polymorphic information content (PIC) and power of exclusion (PE) for parentage testing were estimated.

Results: Great variability in analytical performance was seen among the tested microsatellite markers. Marker AOBR48, for example, proved to be the marker with the highest polymorphic information content. Analysis of accessions from the germplasm collection using microsatellite markers indicated that cashew and a commonly used dwarf clone likely have distinct origins, since they were separated into different groups based on similarity coefficients. Additionally, A. microcarpum, used as an outgroup control, clustered with accessions of the giant type. An F1 population derived from a cross between the dwarf cashew variety (CCP1001) and the giant type (CP 96) was used to map these microsatellites. Among the hundred new markers developed in this study, 11 showed segregation of alleles from the female parent (CCP 1001) in the F1 population, while 21 showed segregation of alleles from the male parent (CP 96). Only three of the 100 tested markers were fully informative showing segregation of alleles from both parents in the F1 population. In total 29 markers could be mapped in this population and 11 markers were positioned in both, the male and female maps.

Conclusions: An initial set of microsatellites was developed for the Cashew tree. These new markers can be useful for a number of applications in germplasm analysis and breeding. The identification of duplicate accessions in the current germplasm collection, the study
of genetic diversity in natural populations, represent immediate potential applications to better understand the existing diversity available to breed better clones. Genetic mapping of QTLs for some economically important traits such as increased yield and quality of fruits and cashew, and resistance to diseases could be future targets provided a higher marker density is achieved.

Promoting a functional and comparative understanding of the conifer genome- implementing applied aspects for more productive and adapted forests (ProCoGen)

Carmen Díaz-Sala, Teresa Cervera and Patricio Arrillaga

1Dpto. Biologia Vegetal, Universidad de Alcalá, 28871 Alcalá de Henares, Madrid, Spain; 2Dpto. Ecología y Genética Forestal, CIFOR-INIA, 28040 Madrid, Spain.

E-mail: cervera@inia.es

BMC Proceedings 2011, 5(Suppl 7):P158

In the midst of a climatic change scenario, the genetics of adaptive response in conifers becomes essential to ensure a sustainable management of genetic resources and an effective breeding. Conifers are the target of major tree breeding efforts worldwide. Advances in molecular technologies, such as next-generation DNA sequencing technologies, could have an enormous impact on the rate of progress and achievements made by tree breeding programmes. These new technologies might be used not only to improve our understanding of fundamental conifer biology, but also to address practical problems for the forest industry as well as problems related to the adaptation and management of conifer forests. In this context, the FP7-KBBE-2011-5 project "Promoting a functional and comparative understanding of the conifer genome- implementing applied aspects for more productive and adapted forests" (ProCoGen), granted in 2011 by the European Commission, will address genome sequencing of two keystone European conifer species. Genome re-sequencing approaches will be used to obtain two reference pine genomes. Comparative genomics and genetic diversity will be closely integrated and linked to targeted functional genomics investigations to identify genes and gene networks that efficiently help to develop or enhance applications related to forest productivity, forest stewardship in response to environmental change or conservation efforts. The development of high-throughput genotyping tools will produce an array of pre-breeding tools to be implemented in forest tree breeding programmes. ProCoGen will also develop comparative studies based on orthologous sequences, genes and markers, which will allow guiding re-sequencing initiatives and exploiting the research accumulated on each of the species under consideration to accelerate the use of genomic tools in diverse species. ProCoGen will also consolidate fragmented activities developed by European research groups involved in several ongoing international conifer genome initiatives and contribute to strengthening international collaboration with North American initiatives (US and Canada). Partners involved in this project are:

Dof proteins are a family of transcription factors specific to the plant kingdom that contain a particular class of zinc finger DNA binding domain. Members of this family are involved in the regulation of genes related to a plethora of metabolic processes including stress or hormone response, seed and endosperm development, flowering, carbohydrate metabolism, and cell or tissue specificity. Dof proteins and encoding genes were characterized in several plant species. Nevertheless poplar is the only woody species whose Dof genes were better characterized. The recent availability of the Eucalyptus grandis genome and transcriptome, along with transcription factor databases of several plant species allowed us to identify and run a valuable comparative analysis of the Dof protein family in this tree. These species included Arabidopsis thaliana, Arabidopsis lyrata, Carica papaya, Populus trichocarpa, Vitis vinifera, Sorghum bicolor, Chlamydomonas reinhardtii, Oryza sativa indica and Zea mays. The phylogenetic relationships among Dof proteins from E. grandis and Arabidopsis thaliana - a popular model for studying the genomics of many plants - is a fundamental step to unravel functionality of new Dof genes not yet characterized. Twenty-three distinct DNA sequences were predicted to belong to the Dof gene family after the analysis of the complete fragmented available genome of E. grandis. The deduced protein sequences of 22 members do contain a conserved Dof domain. One sequence seemed to have lost the conserved Dof domain, suggesting it to be a pseudogene or to present an activity not directly linked to the Dof family. Gene structures, including exon/intron positions, and amino acid sequences were predicted for each gene based on the available E. grandis transcriptome. In order to determine the relationship and function of the genes putatively encoding Dof proteins, we carried out a phylogenetic analysis with 43 Dof protein sequences from A. thaliana. Our analysis allowed us to classify the E. grandis Dof sequences into five groups of orthologous genes. Gene expression analysis via real time, quantitative PCR was also conducted with ten of the E. grandis Dof genes, using samples obtained from flowers, leaves and vascular tissue. Generally, Dof steady-state mRNA levels were higher in E. grandis vascular tissues, with more reduced levels in flowers. Dof genes showed an increase in steady-state mRNA levels after hormone signaling, and reduced levels following abiotic stress. This is the first study that aimed the identification of Dof genes in E. grandis which are possibly involved in numerous plant metabolic processes. The phylogenetic relationship to A. thaliana counterparts and the patterns of mRNA accumulation in E. grandis allowed us to speculate on possible roles for some of the Dof-encoding genes.

Iron-sulfur [Fe-S] clusters are prosthetic groups required to maintain life processes including respiration, photosynthesis, metabolic reactions, sensing, signaling, and gene regulation. In plants, the biogenesis of Fe-S proteins is compartmentalized and adapted to specific needs of the eukaryotic and photosynthetic cell. Although critical to many fundamental metabolic pathways and drastically affecting plant adaptability and productivity, Fe-S proteins were never investigated in woody species. Eucalyptus grandis is an important economical tree widely cultivated in subtropical regions that suffers under low temperature stress. Here we describe a transcriptional analysis of the E. grandis NFS1, ISU1 and ISA1, three genes involved in the biogenesis of [Fe-S] clusters. Microarray analyses were carried out for the comparison of global gene expression in leaves and vascular tissues (xylem) of E. grandis and vascular tissues of E. globulus. In general, leaves from E. grandis demonstrated higher expression of these genes than xylem. EgrISU1 had a constitutive expression in E. grandis, but its expression pattern was higher in this species than in E. globulus xylem. Differences observed in the relative gene expression profile between xylem tissues from the two Eucalyptus species suggest that these genes may be implicated in the contrasting phenotypic characteristics of their wood. The response of these genes to a series of hormonal and stress signals over E. grandis seedlings was also evaluated by RT-qPCR. After the chilling treatment of seedlings, EgrNFS1 and EgrISU1 showed 6 to 8-fold and 0.6 to 1.7-fold increase respectively; and EgrISA1 exhibited a drastic 69 to 114-fold increase. These data are the same observed in Arabidopsis microarrays available in GeneVestigator database. These results suggest that (i) NFS1 and ISA1 may be related to the cellular response to stress caused by chilling, and (ii) the increase in the expression is probably due to sulfur metabolism. A time-course chilling experiment was also carried out. The ISU1 gene expression was higher in the first two hours of treatment and decreased right after that period. The ISA1 gene, which showed the highest expression in the previous experiment, didn’t show significant differences in the expression pattern during the 16 hours of chilling, as well as the NFS1 gene. Our data indicated that Fe-S proteins are possibly involved in the recovery of plants after chilling stress.
One-year old *Pinus radiata* seedlings were inclined during 15 days (d) and transversally cut at 5d, 8d and 15d. Stem slices were stained using a solution of phloroglucinol (2%). From these preparations, wall thickness (28) and cell diameter (2C) of xylem cells were measured.

E-mail: efatemeh.maghuly@boku.ac.at

BMC Proceedings 2011, 5(Suppl 7):P162

**Background:** *Jatropha curcas*(Euphorbiaceae) is cultivated for harvesting the unique oil contained in its seeds, which can be used as raw material for the production of biodiesel [1]. The seed cake remaining after pressing can not be used for animal feed, because it contains toxic proteins and other compounds, e.g. curcin, phorbol esters. The development of genotypes better suited for the production of biodiesel showing lower levels of toxic/allergenic proteins is being hampered by a lack of understanding the a) metabolic pathways and enzymes leading to the production of fatty acids during seed development and b) role of proteins deposited during seed development. In recent years the field of proteomic research has become a fast growing discipline with high relevance to biological sciences.

While genomic and transcript-profiling studies have provided a wealth of information about different plant developmental processes, there is growing awareness that the abundance of mRNA transcripts is not always representative of protein levels and that mechanisms of post-translational regulation must also play an important role.

Proteomics is a systems biology based approach investigating the whole expressed proteins at a given time point and under certain condition [2]. It has been shown to be a valuable tool for studying the biology of living organisms and their interaction with the environment in post genomics area. Proteomics has been shown to have potential values to deliver knowledge about complex biochemical processes and is being used in various fields of modern botany and agriculture like plant biomarker discovery related to resistance as well as drought and water stress. Furthermore proteomics offer major advantages linked to its high throughput capacity and its ability to perform simultaneously the analysis of hundreds of proteins from the same samples.

**Methods:** The method of choice for proteome analysis is the combination of high resolution protein separation like two dimensional gel electrophoresis (2-DE) with tandem mass spectrometry (MS/MS) identification of proteins. The two dimensional gel electrophoresis separates proteins based on their isoelectric points (isoelectric focusing) and in a second dimension based on their molecular weight [3]. In this study a proteomic approach was conducted in order to identify the expression patterns of interesting proteins during seed development, as well as toxic and/or allergenic proteins in Jatropha, 2-DE coupled with mass spectrometry and de novo sequencing, were employed to analyze whole seed proteins of six developmental stages, covering the essential ontological phases of these important plant organs.

**Results and conclusions:** In 2-DE analyses it was possible to identify 100 non-redundant protein spots. Identified proteins belonged to different functional classes, including proteins involved in metabolism, protein destination and storage, and energy metabolism, which were highly representative.

The significant change in abundance of protein spots during the different developmental stages of seeds indicated that several pathways were involved in the biosynthesis of these interesting compounds, but vary during the growth phases of plant organs, in this case seeds.

**P163 Cloning and Functional characterization of the promoter of a high affinity potassium transporter gene from Eucalyptus grandis**

Carolina Costa1, Flávio Tetsuo Sasaki2, Juliana Bravo3, Ivan Maia*1

1IB - UNESP – Botucatu, Brazil; 2IB-UNESP-Botucatu, Brazil

E-mail: igmaia@ibb.unesp.br

BMC Proceedings 2011, 5(Suppl 7):P163

The characterization of organ/tissue-specific promoters is of great interest to transgenic production. The construction of expression cassettes containing tissue-specific promoters is a viable alternative to limited transgene expression to specific organs and cell types. In this context, the purpose of this study was to functionally characterize the promoter of a *Eucalyptus grandis* gene encoding a high affinity potassium transporter (named EgHAK) shown to be specifically expressed in roots. For that, the 5' flanking region of *EgHAK* (1.3 kb) was cloned and transcriptionally fused to the b-glucuronidase reporter gene (GUS), and then used to transform tobacco leaf discs. Histochemical analysis of GUS activity in transgenic plants showed that GUS staining was mainly detected in vascular tissues of leaf and root. To investigate the response of the...
studied promoter to potassium starvation, a hydroponic system was employed. In this case, enhanced GUS staining was observed in the roots of plants starved for 6 days when compared to control ones. Moreover, a weak induction of the promoter at low potassium conditions was observed using fluorimetric assays. Thus, our results indicate that, in a heterologous system, the studied promoter shows preferential expression in roots in the absence of potassium.

Identification of potential transcriptionally active Copia LTR retrotransposons in Eucalyptus
Helena Marcon1,2*, Douglas Domingues1, Celso Marino1*
1Departamento de Genética, UNESP, Botucatu, São Paulo, Brazil; 2IAPAR, Londrina, Paraná, Brazil
E-mail: clmarino@ibb.unesp.br

Background: Long Terminal Repeat retrotransposons (LTR-RTs) represent the most abundant genomic component in all plant genomes thus far investigated. They are transposable elements that replicate through a “copy/paste” mechanism that relies on reverse transcription and integration of a RNA intermediate. Plant LTR-RTs can be divided into two major superfamilies: Copia and Gypsy[1]. LTR-RTs have impact on genome size variation, as well as in the expression of adjacent genes in their host genomes, providing a “genomic plasticity”[2]. Their transcription was believed to be extremely repressed in plants. However, despite their potential mutagenic and deleterious effects, LTR-RTs were proven to be transcriptionally active in several plant species[3].

Eucalyptus is one of the most commercially important forest genus in the world, due to their superior growth, broad adaptability and multipurpose wood properties. Most molecular studies in Eucalyptus are focused on cellulose production and wood development, and there are few works on genome composition, structure and evolution. Pinus and Populus, the tree genera with most available genomic resources, have several works analyzing their repertoire of LTR-RTs [i. e 4, 5], but only one study characterized LTR-RTs in Eucalyptus[6], with no detailed manual checking or phylogenetic analysis. Here, we used FOREST database as a starting point to identify transcriptionally active Copia LTR-RTs in Eucalyptus, that were further analyzed regarding their in silico expression, evolutionary diversity, and distribution in public genomic databases.

Methods: A previous survey with 88 CopiaLTR-RTs from diverse plants defined six major common evolutionary Copia lineages [7]. The 22 Arabidopsis thaliana families analyzed in that study were used as queries to the identify Eucalyptus EST sequences related to Copia elements in FORESTS database [8], by BLASTx (e-value >1e-50). Sequences were then analyzed in RepBase [9] to confirm their similarity to Copia LTR-RTs. EucalyptusESTs with >200bp of copia-like retrotransposon fragments were used to identify complete copies in Eucalyptusgrandis genome v 1.0 in a BLASTn search (identity >80%; in a region >250bp). We picked up 10000bp surrounding the aligned region, that were analyzed usingLTR-Finder[10] and LTR_STRUC[11]. Full-length LTR-RTs were then used as queries in GenBank to retrieve related EucalyptusEST sequences (>200bp; >80% identity). Phylogenetic analyses using the reverse transcriptase of these elements (alignment in MUSCLE; Maximum Likelihood method, bootstrap 1000 replicates) were done using MEGA 5.01[12].

Figure 1(abstract P164) Phylogenetic tree of Copia LTR-RTs elements. Based on Du and collaborators (2010).
Results: Stem, calli and seedlings were used to generate cDNA libraries from a forest genome database with most EST sequences, in this CoPia LTR-RT search. We identified 20 consensus sequences (total: 36 ESTs) from 3 tissues, roots, leaves and flower-buds. We also identified 29 ESTs in GenBank from xylem, root apex and cold-stressed plants (Table 1). Using EST data, we identified six full-length retrotransposon families that had different copy numbers in the Eucalyptus genome, estimated by BLAST searches (cutoff 1e-50). Copy number ranged from 24 to 262 (Table 1). Phylogenetic analyses showed that they are members of the Alc, Angela, GMR and Ivana evolutionary lineages (Figure 1). Alc was the evolutionary lineage encompassing families with highest and lowest copy number (Table 1).

Conclusion: In summary, the present data demonstrate the potential impact of future studies on functional and genomic analysis of LTR-RTs in Eucalyptus. This is the first characterization of full-length CoPia LTR-RTs families in Eucalyptus genome with potential transcriptional activity, giving insights about phylogenetic diversity and copy number variation of retrotransposons in this tree.

BMC Proceedings 2011, 5(Suppl 7):P165

Background: Due to their very high economic importance, Eucalyptus tree species are among the most planted hardwoods in the world with over 20 million hectares. However, as long-lived evergreen species, this genus is particularly exposed to cold. Frost tolerance varies among species and is inversely correlated to productivity. The AP2/ERF gene family includes developmentally and physiologically important transcription factors characterized by the presence of the AP2/ERF DNA-binding domain. AP2 proteins contain two AP2-like domains and RAV family proteins contain one AP2 domain and one RAV domain. ERF family proteins exhibit only one AP2 domain and are further divided into the DREB subfamily and the ERF subfamily [1]. The CBF/DREB1 protein differ from the other DREB proteins by the presence of “signature sequences” (KKPxRKRKxFxETRHP and DSAWR) flanking the DNA-binding AP2 domain [2]. The DREB factors recognize the C-repeat or dehydration response element (DRE) in the promoters of low temperature and/or water deficit responsive genes and would play a crucial role in response to abiotic stresses. CBF/DREB1 are the key regulators of the cold-regulated (COR) gene family. So far CBF transcription factors have been mainly characterized in model plants such as Arabidopsis, but lately they were identified in several tree species including Eucalyptus [2]. The Eucalyptus cold tolerance was greatly improved in our hands when two genes from the four CBF members isolated from a tolerant species E. gunnii were individually constitutively overexpressed in the frost sensitive E. urophylla x E. grandis hybrid [3]. In the present study E. grandis AP2/ERF family genes were identified based on the presence of putative encoding AP2-domain(s) and were studied with regard to the model herbaceous Arabidopsis as well as the main sequenced woody plants. Within this family, a part of the study focused on the CBF/DREB1 subfamily which was compared to the four genes already characterized in E. gunnii [2].

Methods: We used the available annotated E. grandis genome sequence at phytome (http://www.phytome.net/eucalyptus.php), the Arabidopsis thaliana AP2/ERF family downloaded from the DATF (Database of Arabidopsis Transcription Factors) database website (http://datf.cbi.pku.edu.cn/), and the sequences of AP2/ERF gene family from the grapevine, and the poplar obtained from several publications. In order to get the exhaustive gene AP2 family and the location of the genes of the E. grandis genome, we used Scipio [4]. Every identified protein was analyzed for structural motifs by scanning them against PROSITE patterns and profiles (http://www.expasy.org/prosite) and against Pfam (http://pfam.sanger.ac.uk/) to make sure of the presence of AP2 and/or the B3 domains. A fine correction of the predicted AP2/ERF proteins was performed. In order to identify all the members of CBF subfamily, a search within the E. grandis annotated AP2/ERF family was performed using consensus sequence including the two highly conserved signatures (PKPKPAGR and DSAWR) surrounding the DNA-binding AP2-domain. As a check, we confirmed by blasting the sequences on the NCBI blast page. From a multiple alignment analysis performed with Clustal W, the phylogenetic trees were generated using MEGA version 5. The resulting phylogenetic trees were based on the maximum likelihood (ML) method [5].

Results and main conclusions: Based on the sequence alignment, the phylogenetic analyses, and the known criteria described in literature, this study revealed that the annotated AP2 genes from E. grandis were divided into the four subgroups already described for Arabidopsis (DREB, ERF subfamilies, AP2 subfamily and RAV subfamily). The two subfamilies DREB and ERF were separated according to the similarity of the sequences of the AP2/ERF domain and to the amino acid at 14 and 19 positions. Distribution of the DREB members in the four dicotyledonous plant genomes (Vitis, Arabidopsis, Populus and Eucalyptus) shows similarities between grapevine and E. grandis except for the A1 subgroup which contains both to the CBF and ERF genes. Interestingly this group is much larger in E. grandis compared to the three other plant species. The 17 CBF genes (including one pseudogene) identified on E. grandis genome exhibit a very good conservation when compared to the E. gunnii CBF genes. The E. grandis CBF genes could be classified into the four groups (a, b, c et d) described for E. gunnii CBF. Most of the EgrCBF were localized on the chromosome 4, one member is on the chromosome 4 and the last two on the chromosome 5.

References
Background: Eucalyptus forests are a competitive and efficient alternative to convert carbon from the atmosphere in cellulose, an important source for paper manufacture and bioenergy production. To obtain transgenic Eucalyptus with important traits improved it is necessary to make modifications in genes that affect the final phenotype. One interesting gene that follows this requisite was recently found: this is the AtSHN2 gene (*Arabidopsis thaliana* SHINE 2). AtSHN2 codifies to a Transcription Factor known as "Arabidopsis SHINE/ WAX INDUCER". Instead of inducing drought tolerance in transgenic rice (*Oryza sativa*), AtSHN2 overexpression causes: i) 34% increase in the cellulose content; ii) 45% reduction in lignin content and iii) increase in wood digestibility (elevated S/G ratio) with no compromise in plant strength and performance [1].

The discovery of AtSHN2 function in plant cell wall formation, led Ambavaram and collaborators [1] to perform other studies and ultimately to propose the following model: AtSHN2 regulates positively MYB transcription factors (TF) related to cellulose synthesis and it down-regulates MYBTFs related to lignin formation. At the same time, SHINE can repress NAC TPRthat controls MYB expression[1].

As a consequence of the interesting phenotype achieved through AtSHN2 overexpression in rice, this work focused on the identification and analyses of AtSHN orthologues in *Eucalyptus*. Bioinformatics tools were used to search for AtSHN similar genes in *Eucalyptus*. Moreover, the expression profile of the corresponding genes in *Eucalyptus* was evaluated to prove their role as AtSHN. To carry it on, the expression experiments were done with flower, leaf and xylem. If the *Eucalyptus* putativeSHINE's has the same function of the AtSHN's, gene expression in flower tissues will be the highest [2]. This is because it is known that AtSHN's genes are preferentially expressed in abscission and dehiscence zones, a phenomenon that usually occurs in lots of flower tissues.

Material and methods: Putative transcription factors of the SHINE family were searched in *Eucalyptus* by comparing the AtSHN amino acid sequences with the *Eucalyptus* genome assembly (obtained from *Eucalyptus grandis* – [http://eucalyptusdb.bi.up.ac.za](http://eucalyptusdb.bi.up.ac.za)). This analysis revealed the existence of two sequences with high similarity to AtSHN proteins. Quantitative RT-PCR assays were carried out to verify the expression profile of these genes in different tissues (leaves, flowers and xylem) of the hybrid variety *E. urograndis* (*E. urophylla* x *E. grandis*). The RNA extraction was carried out following the protocol described by Zeng & Yang (2002) [3]. The qRT-PCR was performed with the SYBR® Green PCR Master Mixkit from *Applied Biosystems*. The Results were analyzed according to the mathematical method described by Pfaffl, 2001 [4].

Plant materials were provided by the International Paper Company, Brazil.

Results and discussion: The comparison of the AtSHN amino acids sequence with *E. grandis* genome revealed the existence of two putative SHN genes in *Eucalyptus* (named EgSHN1a and EgSHN1b). A phylogenetic
analysis showed that these *Eucalyptus* SHN genes are orthologs to the *AtSHN1* of *Arabidopsis thaliana* (Figure 1).

The proteins encoded by *EgSHN1a* and *EgSHN1b* share approximately 58% identity to *AtSHN1* and a conserved gene structure is found between *AtSHN* and both *EgSHN* genes: a single intron is present and located approximately 80 bp from the start codon. In addition, as in *AtSHN1*, *EgSHN* genes contain an AP2 DNA binding domain, which is in accordance to their putative role as transcription factors. More importantly, the domains “mm” and “cm”, which are exclusive of SHN genes, could be identified in the *Eucalyptus* sequences. In the same way that the gene sequence is very correlated between the species, it’s probable that their function are the same two.

Gene expression analysis revealed a higher expression of *EgSHN1a* in flowers (Figure 2). This result is similar to the *AtSHN1* expression profile [2], suggesting a similar function for *EgSHN1a*.

The expression pattern of the gene *EgSHN1b* is being carried on.

**Conclusions:** There are two SHN genes in *Eucalyptus* (*EgSHN1a* and *EgSHN1b*), which are orthologs to *AtSHN1*; the *EgSHN1a* function might be the same of *AtSHN1* as suggested by their similar expression patterns. It is possible that, in *Eucalyptus*, biosynthesis of cuticle and cell wall in abscission and dehiscence zones is regulated by *EgSHN*’s, as already described in *A. thaliana* [1].

The new genes described here are interesting candidate for the development of transgenic *Eucalyptus* cellulose exporter. That’s really good news because *Eucalyptus* forests are a competitive and efficient alternative to convert carbon from the atmosphere in cellulose, an important source for paper and bioenergy production.

**Transgenic *Arabidopsis thaliana* and *Nicotiana tabacum* overexpressing the *Eucalyptus grandis* Cellulose Synthase 3 and its expression pattern in different *Eucalyptus* species and tissues**

1State University of Campinas – UNICAMP, Brazil; 2International Paper

E-mail: goncalo@unicamp.br

**BMC Proceedings** 2011, 5(Suppl 7):P167

**Background:** In Brazil, the forest industry accounts for 4.5% from the Gross Domestic Product and the country is the biggest *Eucalyptus* cellulose exporter. That’s really good news because *Eucalyptus* forests are a competitive and efficient alternative to convert carbon from the atmosphere in cellulose, an important source for paper and bioenergy production.

Figure 1(abstract P167) *Eucalyptus Cellulose Synthase 3* expression pattern. On the top, expression pattern analyzed trough qRT-PCR and, below, the expression analyzed trough Northern-Blot. The tissues studied were leaves and xylem from three different *Eucalyptus* species: *E. globulus*, *E. grandis* and *E. urophylla*. 
The cellulose biosynthesis happens through the **Cellulose Synthase Complex** activity. This complex is composed by different **Cellulose Synthase** genes (*CesA*) that work together in a non-redundant way [1]. It is also known that some of these isoforms act in the primary cell wall synthesis while others, in the secondary cell wall. In this last group there is the gene Eucalyptus Cellulose Synthase 3 (*EgCesA3*), the most expressed *CesA* gene during xylegenesis [2]. Besides, knockout experiments proved that the AtCesA7 (*EgCesA3* ortholog in *Arabidopsis thaliana*) activity is essential for the xylem formation and for plant vertical growth [3].

In front of these evidences, the *EgCesA3* gene had it expression pattern evaluated in leaf and xylem tissues among the three most economic important Eucalyptus species in Brazil: *E. grandis*, *E. globulus* and *E. urophyla*. As demonstrated in this work, the expression experiment provided enough information about the *EgCesA3* function, that’s why this gene was chosen to be overexpressed in model plants (*Arabidopsis thaliana* and *Nicotiana tabacum*). It’s expected increased cellulose content in the transgenic plants xylem.

**Material and methods:** The *EgCesA3* expression pattern was examined through qRT-PCR and Northern-Blot in xylem and leaf from the tree most commercially important Eucalyptus species: *E. grandis*, *E. urophyla* and *E. globulus*. The qRT-PCR was performed using SYBR Green and amplicons with approximated size of 100pb. On the other hand, the Northern-Blot was made with probes containing phosphorous-32 radioactive.

To create transgenic plants with improved cellulose content this work overexpressed the gene *EgCesA3* under the control of the CaMV 35S promoter in *A. thaliana* and *Nicotiana tabacum* through Agrobacterium transformation by floral-spray.

**Results and discussion:** The results show that the *EgCesA3* is strongly more expressed in xylem than in leaves among the three most important economical Eucalyptus species for the Brazilian forest industry (Fig. 1). This data corroborate to the theory that this gene is related to the secondary cell wall formation during the xylem development.

However, it’s necessary to mention that the gene expression data obtained through the northern-blot related to the *E. globulus* leaf can’t be analyzed. This because the amount of RNA used in this sample was different from the others. It can be seen through the rRNA amounts in the RNA electrophoresis (Fig. 1).

Besides, comparing the *EgCesA3* expression pattern between the xylem from the three species studied, it’s possible to conclude that should exist a difference: the *EgCesA3* gene is apparently more expressed in *E. grandis* and *E. urophyla* xylem than in *E. globulus* xylem (Fig. 1). However, this conclusion isn’t distant from doubts: the problem is the large error bars that happened in the experiment. In order to solve it, the qRT-PCR repetition is being carried on.

In front of the *EgCesA3* role in the secondary cell wall synthesis, this gene was overexpressed in model plants (Fig. 2). The genetic modified plants were successfully obtained. Thus, after the generation advance, the homozygous transgenic plants will be evaluated to measure the cell wall chemical composition and morphology.

**Conclusion:** The Eucalyptus Cellulose Synthase 3 function in the secondary cell wall synthesis was confirmed by this work; the cellulose content variation trough the species studied should be a consequence of the Eucalyptus CesA3 expression level.

Transgenic *A. thaliana* and *N. tabacum* overexpressing the *EgCesA3* gene were successfully obtained. The transgenic plants analyses are being performed; however it’s already possible to notice, by empirical view, growth improvement in the transgenic plants in comparison to the wild type.

In silico comparative analysis of glycoside hydrolase (GH) family 10 endo-(1-4)-beta-xylanase genes from *Eucalyptus grandis* and *Arabidopsis thaliana*

Ritesh Mewalal, Desre Pinard, Eshchar Mizrahi, Alexander A Myburg

Department of Genetics, Forestry and Agricultural Biotechnology Institute (FABI), University of Pretoria, Pretoria, 0002, South Africa

E-mail: ritesh.mewalal@ufs.ac.za

**Background:** The hemicellulose xylan constitutes the major non-cellulosic component of plant secondary cell walls. It has been shown...
that xylan adsors to cellulose fibres and also covalently binds a carbon moiety of lignin [1,2]. *Eucalyptus* is an important hardwood tree genus used in the pulp and paper industry and has potential as biofuel feedstock. Xylan removal is expensive and uses environmentally harsh chemical treatments [3]. Previous studies have shown that endo-(1-4)-\beta-xylanase enzymes belonging to glycoside hydrolase (GH) family 10 internally attacks the xylan backbone resulting in shorter xylo-saccharide chains [4]. The recently sequenced *Eucalyptus grandis* genome (DOE-JGI, http://www.phytozome.net) provides a unique opportunity to analyze the native endo-(1-4)-beta-xylanase proteins involved in xylan modification in

Figure 1(abstract P168) Co-phylogenetic analysis of the predicted protein sequences of GH10 family members (E score < 1e-10) in *E. grandis* and *A. thaliana*. Neighbor-joining and 1000 bootstrap replicates conducted in MEGAS. EgrXYN1 refers to Egrandis_v1.0.001952m while AtXYN1 refers to At1g58370 (indicated with bold arrows).
A xylanase, AtXyn1, is predominantly expressed in vascular bundles, and four putative xylanase genes were identified in the Arabidopsis thaliana genome. Plant Cell Phys 2002, 43:759-767.

Expression analysis of DNA methyltransferase and co-repressor genes in Quercus suber phellogen: an attempt to correlate with cork quality

Miguel Ramos1, Margarida Rocheta2, Luisa Carvalho1, José Graça1, Leonor Morais-Cecilio1

1CBA, ISA, Technical University Lisbon, Tapada da Ajuda, 1349-017 Lisbon, Portugal. 2CEF, ISA Technical University Lisbon, Tapada da Ajuda, 1349-017 Lisbon, Portugal.

E-mail: lmorais@isa.utl.pt

BMC Proceedings 2011, 5(Suppl 7)P169

Background: Cork oak (Quercus suber) is one of the most important forest species in Portugal. Cork oak produces a thick cork bark which is harvested for industrial uses. Cork quality is the most important factor that affects its technical performance and economic value. Cork quality is associated with many features, the most relevant being the porosity resulting from the phellogen’s differentiation in filling tissue which will degenerate to lenticels. Good cork has few pores of very thin diameter being the opposite valid for low cork quality. Aiming to understand the mechanisms responsible for controlling of the molecular machinery involved in cork production, namely at the epigenetic level, it is relevant to study the expression profiles of the enzymes involved in DNA methylation in the phellogen.

Methylation of cytosines in the DNA, achieved by DNMT methyltransferases, is one of the most important factors in the regulation of gene expression [1]. In plants three DNMT classes have been identified, each one with its function: the CMT (chromomethylase) class found only in plants, is responsible for maintaining the methylation in CpHgG sequences [2]; the DRM (Domain-Rearranged-Methyltransferase) class is associated with de novo methylation in any context [3]; and the MET class, responsible for the maintenance of methylation in CpG zones [1]. Proteins, such as the DNA methyltransferase-associated protein (DMP1), are known to form stable complexes with DNMTs and act as co-repressors of gene expression. In this work, we report the transcriptional profile of three putative DNA methyltransferase genes from the CMT, DRM and MET classes, and one DMP in Q. suber phellogen of trees producing good or bad quality cork.

Methods: Three Quercus suber potential producers of good quality cork and three producers of bad quality cork were selected. Samples of cork and phellogen were collected from these trees to further estimate cork quality and perform a transcriptional analysis of selected genes. Previously an in silico analysis was performed on a cork oak EST library (COEC, Cork Oak ESTs consortium). Three EST sequences, referred as DNA methyltransferases, and one as DMP1 were selected. Each one was identified and characterized against available databases. Primers were designed to specifically amplify each sequence in real-time-PCR analysis. The actin gene was chosen as internal reference. RNA was extracted from phellogen...
samples, using Spectrum Plant Total RNA kit and cDNA was obtained with Retroscript kit. Gene expression was analyzed in the six phellogen samples, using qRT-PCR in triplicate reactions performed for each cDNA template with each primer pair. The NormFinder algorithm was used to evaluate the gene expression’s stability using the sample 75 as reference.

**Results:** Measurement of cork density allowed forming two groups of trees: (1) three individuals with the lower average density (0.289 g.cm\(^{-3}\) ± 0.037) classified as good cork quality producers, (2) three trees with the highest average density (0.388 g.cm\(^{-3}\) ± 0.036) classified as bad cork quality producers.

Homology search using BLASTP algorithm against available databases showed significant similarities between selected our putatively translated ESTs and known DNMTs (CMT3 - ABW96889, DRM2 - ABW96890 and MET2 - XP_002874265) and DNMT associated proteins (DMAP1-XP_002515237) with e-values of 2e-50, 5e-95, 1e-92, 9e-64, respectively. The expression of the three putative DNMTs and DMAP1 genes was evaluated in the phellogen of both tree groups.

The gene expression stability, evaluated through the NormFinder algorithm, showed values ranging from 0.4 for QsDRM2 to 1.5 for DMAP1. Actin also showed an appropriate value (0.7) to be used as internal control. Bad cork quality tree #75 was used as reference. QsMET2 and QsDMAP1 genes showed the highest expression values, while QsCMT3 and QsDRM2 presented the lowest. Comparison of both group trees revealed that, in average, the expression level of each gene is higher in the bad cork quality group than in the good cork quality group (Fig1).

**Conclusions:** In this work we identified one functional DNA methyltransferase of each class (QsCMT3, QsDRM2 and QsMET2) and the MET1 associated protein (QsDMAP1) in cork oak phellogen. This protein has been described in humans [4] as a co-repressor of gene expression, capable of binding with other regulatory proteins such as histone deacetylases [4] which are also associated with gene silencing. The general tendency of DNMTs to express less in trees able to produce good cork quality suggests a globally lower methylation level and therefore a lower phellogen gene repression. We can hypothesize that gene silencing is higher in bad quality producers, leading to a higher weight of genes whose expression originates defects.

Gene stability analyses lead us to consider QsDRM2 as the most stable, as was already reported in other species. Therefore, this gene may be a good candidate to be used as reference gene, in future real-time-PCR analyses. This high stability seems to indicate that de novo methylation although occurring, has no influence in good or bad cork quality production. Conversely, the more variable expression, and therefore the genes that can potentially affect cork quality are QsMET2 and QsDMAP1 genes.

BMC Proceedings 2011, 5(Suppl 7):P170

Background: The species of the genus *Eucalyptus* are the most planted for the fiber crop in the world. They are mainly utilized for timber, pulp and paper production. Brazil, helped by the favorable weather conditions, appears as a big producer and exporter of eucalyptus derivatives. In 2002, the Brazilian network research of the *Eucalyptus* Genome (Genolyptus) was established with the goal of integrating several academic and private institutions currently working with eucalyptus genomics in Brazil. This project generated around 200.000 ESTs from several tissues and conditions. Consequently, several individual projects have been implemented generating other transcriptome databases, in special, using RNA-Seq technology. In 2010, a draft genome (http://eucalyptusdb.bi.up.ac.za) of the species *E. grandis* was produced by researches of the Joint Genome Institute (DOE-JGI) and the *Eucalyptus* Genome Network (EUCAGEN). The main goal of this work is to develop an Eucalyptusdatabase (http://www.lge.ibi.unicamp.br) integrating public and private data in a friendly and secure web interface with bioinformatics tools that allowing the users perform complex searches.

Results and discussion: First, the public and private ESTs (130,290 from Genolyptus and 36,981 from NCBI) were assembled producing 48,760 unigenes (17,795 contigs and 30,765 singlets). Basically, the bdtrimmer [1] and CAP3 [2] programs were used to perform sequence trimming (exclude vector, ribosomal, low quality and too short reads) and sequence assembly, respectively. The autofact pipeline [3] was used to perform an automatic annotation of the assembled unigenes based on BLAST [4] searches, e-value cutoff of 1e-5, against some protein databases, including: non-redundant (NR) database of NCBI, uniref90 and uniref100 – databases containing only curated proteins [5], pfam – database of proteins families [6], kegg – database of metabolic pathways [7] and Gene Ontology (GO) – database of functional annotation [8].

The Genomic and Expression Laboratory at State University of Campinas (http://www.lge.ibi.unicamp.br) sequenced ten RNA-Seq libraries from four species (*E. urophylla*, *E. grandis*, *E. globulus*, *E. grandis* and *E. urophylla*) using the Illumina/Solexa technology. Additionally, three RNA-seq libraries [9] were downloaded from NCBI (SRA – sequence read archive). All RNA-seq reads were aligned against the assembled unigenes and genome assembly using the SOAP2 [10] and TopHat [11] aligners, configured to allow up two mismatches, discard sequences with ‘N’s and return all optimal alignments. In order to perform a differential expression analysis between ESTs or RNA-seq libraries some normalization pipelines and statistical tests have been implemented. From ESTs, the differentially expressed genes between libraries were performed applying AC test [12] in assembled unigenes. The results are available to the users by a web interface (called Electronic Northern) that allows searches by gene or library name. Furthermore, it is possible to compare the gene expression between two or more libraries. From the RNA-seq libraries, the DEG-seq software [13] was used to perform normalization and statistical analysis considering 99% of confidence rate (cut-off of 0.01).

To integrate all data described above, we developed a web site (Fig. 1) hosted in a Fedora Linux machine with MySQL database server. The web interface is based on a combination of CGI scripts using PERL language (including BioPerl module) and the Apache Web Server. The site contains many bioinformatics tools allowing the user perform keyword or local BLAST search in assembled unigenes. Also it is possible to connect these results with gene expression analysis. Moreover, the Gbrowse software (Generic Genome Browser) (Fig. 2) was used to visualization the data in a genomic context, integrating the different information by clickable tracks. The top track is the reference genome assembly and the other tracks correspond to assembled unigenes and RNA-seq data mapped into reference.

BMC Proceedings 2011, 5(Suppl 7):P172

The family of fagaceae, comprises about 900 species, among them the best-known group of this family is the oaks, genus Quercus, that are commonly used as timber or for cork production. Cork is produced by Q. suber, an evergreen oak with major economic and environmental importance for Mediterranean region, in particular for Portugal that is the leading producer of this material.

Besides, the economic importance of cork production and cork manufacturing, little attention has been paid to the molecular mechanisms underlying wood and cork formation as well as cork quality. To overcome this constraint, an international partnership (SuberGene) was established 2008, involving Portuguese and French research institutions and one Producer’s Association organization (FJLF). The main driving force of this partnership is to join efforts and complementary skills to unravel the molecular mechanisms underlying cork formation and decipher the structural polymorphisms and regulation network that determine cork quality.

A non-normalized cDNA library of developing phellem (DP) was produced and 5,000 clones were sequence both ends using Sanger technology. More than 6500 good quality ESTs were deposit at GeneBank. DP transcriptome was also assessed by pirosequencing (454FLX Titanium, Roche) generating more than 200,000 reads. Sequencing data (238,911 ESTs) data were assembled into 69,559 contigs. Suberin biosynthesis genes such as Glycerol-3-phosphate acyltransferase and Omega-hydroxypalmitate O-feruloyl transferase are among the more expressed genes in DP tissues. More than 2,800 putative SNPs were detected in transcriptome of DP and were assessed, by 2D-PAGE, and mass spectroscopy. In order to get more information about the gene structure of genes related with the suberisation of cork cell-wall, one Q. suber BAC library have been constructed, and are being characterized. Clones harboring genes of interest were identified by screening high-density filters of this BAC library.

These resources provides us with valuable tools to study the nature of the molecular machinery involved in cork formation, and most importantly with the players involved in the variability of cork characteristics. Future ongoing approaches and the impact of these finding will be discussed.

Acknowledgments: The authors would like to thank the valuable contribution of actual and former members of the involved groups and institutions: Susana Araújo1, Victor Carocho1, Cláudio Capitão2, Clara Graça2, Joana Amado7, Céline Lalanne7, Nathalie Ladoue7, Céline Noirot8, Elisa Prat2, Sonia Vautrin9, Joelle Fourment9.

This work was partially supported by FCT (Portugal) (PTDC/AGR-GLP/101785/2008). Authors also acknowledged FJLF that provided the plant material necessary for this work.

**BMC Proceedings 2011, 5(Suppl 7):P173**

**Background:** Micro RNAs (miRNAs) are a class of small (~21 nucleotide) non-coding RNAs that recently gained much attention due to their perceived role as master regulators of gene expression in Eukaryotes, responsible for fine tuning gene expression regulation and, in plants, has been shown to be involved in a diverse range of biological processes such as plant development and architecture, flowering, cell differentiation and response to biotic and abiotic stresses [1]. The repertoire of expressed miRNAs differs among cell types, tissues, development, environmental condition, etc [2]. Notwithstanding, the exact function of thousands of miRNAs sequences present in miRBase (http://www.mirbase.org/) is not elucidated. At this point, discovery and profiling of new and conserved miRNAs are critical in the attempt to understand their function and mechanism. Deep sequencing through next generation sequencing is the methodology of choice for this purpose as its ultra high throughput permits a comprehensive interrogation of the small RNA transcriptome, permitting de novo identification and relative quantification of different small RNA species [3].

Due to its economic importance the *Eucalyptus grandis* genome has been sequenced by JGI and the annotation of miRNAs is pivotal. In order to provide the first large scale experimental characterization of Eucalyptus miRNAs we performed an illumina deep sequencing run that allowed us to discover and quantify the miRNA levels in two different tissues – xylem and leaves. Additionally, to get insights of the observed phenotypic differences in wood quality among *Eucalyptus* species, we characterized the xylem small RNA transcriptome of two different *E. globulus* individuals and integrated the results to catalog conserved and *Eucalyptus* specific miRNA gene families.

**Materials and methods:** Four biological samples were used: xylem from two *E. globulus* genotypes, xylem and leaf from BRASUZ1 *E. grandis*, the one currently being sequenced by JGI. Total RNA extraction was performed with CTAB protocol to a total amount of 10 mg per sample. Fraction of small RNAs were barcoded to be sequenced in a single flow cell in Illumina GA II Sequencing System by Fasteris [http://www.fasteris.com]. A computational pipeline was specifically developed to process the deep sequencing data. The pre-processing step cleans the sequences by quality screening, adapter sequence removal, contaminant checking. Cleaned reads were sorted according to size, quantified (tag counting) and used to create an additional set of non-redundant sequences by quality screening, adapter sequence removal, contaminant checking. Bowtie was used to map sequences against the genome reported, 23,54% failed to align and 5,91% reads per day and the ability to analyze and translate quickly this data permits a comprehensive interrogati on of the small RNA transcriptome, permitting de novo identification and relative quantification of different small RNA species [3].

Due to its economic importance the *Eucalyptus grandis* genome has been sequenced by JGI and the annotation of miRNAs is pivotal. In order to provide the first large scale experimental characterization of Eucalyptus miRNAs we performed an illumina deep sequencing run that allowed us to discover and quantify the miRNA levels in two different tissues – xylem and leaves. Additionally, to get insights of the observed phenotypic differences in wood quality among *Eucalyptus* species, we characterized the xylem small RNA transcriptome of two different *E. globulus* individuals and integrated the results to catalog conserved and *Eucalyptus* specific miRNA gene families.

**Materials and methods:** Four biological samples were used: xylem from two *E. globulus* genotypes, xylem and leaf from BRASUZ1 *E. grandis*, the one currently being sequenced by JGI. Total RNA extraction was performed with CTAB protocol to a total amount of 10 mg per sample [4]. Fraction of small RNAs were barcoded to be sequenced in a single flow cell in Illumina GA II Sequencing System by Fasteris [http://www.fasteris.com]. A computational pipeline was specifically developed to process the deep sequencing data. The pre-processing step cleans the sequences by quality screening, adapter sequence removal, contaminant checking. Cleaned reads were sorted according to size, quantified (tag counting) and used to create an additional set of non-redundant sequences (using uclust). Bowtie was used to map sequences against the genome reported, 23,54% failed to align and 5,91% mapping positions in the genome were extended by 150 bases to be used as input to predict secondary structure (miDeep) to test for stem loop structure of miRNA precursors. Northern blot hybridization is being used for experimental validation of some conserved and potentially new *Eucalyptus* miRNAs sequences.

**Results and conclusions:** Total number of reads was 6,104,498 ranging from 1,115,404 to 1,766,355 per sample – 36 nt average size. After pre-processing, total number of sequences was reduced to 1,980,958. As expected, read size distribution has two main peaks at 21 and 24 nt. Comparative analysis of size distribution interestingly shows higher abundance of the 24 nt fraction for all samples, being up to 3.75 times higher than 21 nt. The 24 nt small RNAs are predominantly small interfering RNAs (siRNAs) which are involved in RNA-directed DNA methylation in gene and transposon silencing. Putting it all together, reads from four samples resulted in 169,642 unique sequences mapped against the genome. From that, 70,55% had at least one alignment to the genome reported, 23,54% failed to align and 5,91% mapped to multiple loci, indicative of repeat regions. Mapping 20-22 nt reads against the reference genome revealed that BRASUZ1 had more reads mapping to its own genome than the other samples, totaling 95% for leaves sample and 91% for the xylem. *E. globulus* samples showed a reduced percentage of mapped reads, around 85%, corroborating the existence of interspecific variability. Besides that, the relative abundance among the three xylem samples reinforces the variability also in the expressed repertoire of small RNAs.

**Annotation of plant miRNAs** was done meeting a set of strict criteria, particularly a proper secondary structure of the precursor [5]. The positions in the genome with a mapped reads were extended to 300 bases and fed to the program miDeep [6] to test for the compatibility of precursor hairpin. At least 38 sequences mapped were positive under these premises.

Conserved *Eucalyptus* miRNAs were identified by similarity searches against the miRBase. A total of 206 distinct *Eucalyptus* sequences showed significant similarity (at most one mismatch) to an orthologous sequence, confirming the presence of 36 different mir genes families, including many of its isoforms.

**Quantitative differences** in miRNA abundance were probed by pairwise comparison of tag counts contrasting intraspecific, interspecific and tissue-specific analysis. Results revealed that the most similar small RNA repertoire are between intraspecific samples and, the least, between tissue specific. Tissue specific differential expression analysis shows that around 36% of the conserved miRNAs sequences observed in each tissue was mutually exclusive and the ones present in both samples vary up to two-fold (p-value<0.05).

Experimental validation is being carried out by northern blot hybridization and preliminary results validated new and conserved miRNAs, such as mir 156 and mir 172.

**Next-generation gene catalogues and genomics tools focused on forestry research**

Philippe Rigault

Gyde Inc,1363 av. Maguire, Québec, QC G1T 1Z2, Canada

E-mail: prigault@gydele.com

**BMC Proceedings 2011, 5(Suppl 7):P174**

Gyde is developing reference gene catalogues and genomics resources targeted at forestry research, leveraging its unique bioinformatics expertise in next-generation sequencing. Next-generation sequencing technologies have revolutionized the field of genomics and have reached the capacity to generate enough quality data to sequence and assemble thousands of genomes and gene catalogues per year. These extraordinary opportunities are currently limited by challenges in data analysis which hinder the translation from raw sequencing data to applications in research and in the field. There is an enormous gap between an instrument capacity to produce millions of reads per day and the ability to analyze and translate quickly this data into usable information and value-added sets for genomics research. One particular limitation stems from the current state of assemblers which produce crude contigs and scaffolds that need considerable editing in order to obtain contiguous, gene-oriented, full-length, artifact-free
annotated sequences desirable for the production of quality tools for genomics research. Researchers also lack tools to rapidly integrate and visualize their own data and collaborate in a user-friendly way. Finally, the ability to produce gene catalogues for thousands of samples calls for a new generation of tools to conduct large-scale comparative genomics studies between and within species. Gydle has developed a complete suite of proprietary bioinformatics tools to address many of the challenges associated with next-gen sequence analysis. A survey of these tools will be presented, which include innovative raw data filtering, rapid and accurate DNA alignment and gene-oriented assembly software, automated and interactive visualization tools for sequence correction and annotation. These tools enable users to process from start to finish a typical next-gen sequencing run in a user-friendly way in a matter of minutes to hours instead of weeks. Users can then visualize their results, edit sequence assemblies and annotations and identify features such as sample-specific expression patterns, SNPs, unspliced introns and alternative splicing events, handling information from hundreds of millions of reads on their workstation or laptop computer. We intend to make these bioinformatics tools available commercially in the near future.

Applying these bioinformatics tools, we combined sequencing data generated by Gydle with publicly available data to produce curated reference gene catalogues for species of interest to the forestry industry, which currently 35 tree species including 7 pinus, 3 picea, 3 eucalyptus, 2 poplar and 5 oak species. Gydle gene catalogues also include over 50 other plant species of agricultural and medicinal interest as well as gene catalogues for species ecologically related to trees such as insects, endophytes, fungi, and microbiota. We intend to make these catalogues available commercially in addition to offering the possibility for researchers to integrate their own data with these catalogues privately.

We used these reference gene catalogues to produce species-specific and cross-species value-added genomics resources such as:
- reference gene sequences covering biochemical pathways involved in growth, wood formation, climate adaptation, biofuel production, and secondary metabolites of interest to pest resistance and human health - curated amino-acid databases to improve proteomic and metabolomic identifications
- SNP sets and designs of high-throughput genotyping assays such as Illumina GoldeGate/Infinium for marker discovery and genomic selection.
- reference sets and tools for gene expression studies by RNA-seq and microarrays.

Examples of gene catalogues, cross-species analysis and value-added sets will be presented.

BMC Proceedings 2011, 5(Suppl 7):P175

Background: The Eucalyptus wood is one of the most important raw materials for pulp and paper industry. Brazil is currently the first producer of short-fiber pulp and sixth in total production of cellulose. To maintain the industrial competitiveness, investment in genomic research started in 2002 with the GENOLYPTUS project (Brazilian Network of Eucalyptus Genome Research). Recently, a new transcriptome library was generated using Next Generation RNA Sequencing by Illumina’s sequencing by synthesis technology.

Different species of Eucalyptus are recognized for their superior characteristics in terms of growth, wood quality and resistance to different types of stress (1). Such features are probably driven by the coordinated expression of numerous genes involved in processes of structural and regulatory genes in xyleogenesis. Therefore, the main purpose of this study is to identify genes and key metabolic compounds directly involved in wood quality, as well as transcription factors involved.

An extensive data mining in the RNAseq database was conducted to identify sequences over expressed in xylem and those that were down regulated in comparison with non xylem tissues. Such genes were sorted in decreasing order of their statistical pipeline were applied using http://www.biomedcentral.com/1753-6561/5?issue=S7

Methods: Genolymphus Sanger sequenced ESTs (167,271) and NCBI ESTs (36,981) were assembled using the program CAP3 (2). All unigenes were automatically annotated using BLAST (3) (e-value cutoff of 0.01) against protein databases, including: non-redundant (NR) database, uniref (4), pfam (5) and keg (6). Moreover, a functional annotation using the BLAST2GO software was performed (7). The RNA-Seq reads produced from three different xylem libraries (Eucalyptus globulus, E. grandis and E. urophylla) were aligned against the assembled unigenes using the SOAP2 aligner (8) configured to allow up to two mismatches, discard sequences with “N”s and return all optimal alignments. In order to perform the differential expression analysis between libraries, a normalization and statistical pipeline were applied using DEG-seq (9) software considering a 99% confidence rate (cut-off of 0.01).

From this analysis we obtained

Figure 1(abstract P175) Functional annotation using the BLAST2GO software.
xylem genes and transcription factors differentially expressed between the three species.

**Results and discussion:** The assembly produced 53,412 unigenes (18,096 contigs and 35,314 singlets). The xylem libraries produced a large number of RNAseq reads (35bp). About 28 million reads were produced for the *E. globulus* library, 25 million for *E. grandis* and 25 million for *E. urophylla*. About 2% of reads were discarded after filtering. Most part of RNAseq reads mapped into the new EST assembly: 69.27% for *E. globulus*, 71.97% for *E. grandis* and 67.90% for *E. urophylla*. As a result, 33,599 unigenes were aligned to the RNAseq libraries. The functional annotations (Figure 1) show percent of genes related to the most relevant GO categories represented in each of the species pairs studied for Biological Process, level 3.

In the *E. globulus* X *E. grandis* comparison, most genes are in the macromolecule metabolic process category that includes genes for pectin, cellulose and hemicellulose metabolism and also transcription factors involved in such pathways. Over 10% of these genes are over-expressed in *E. globulus*. Over 30% of the genes are over-expressed in *E. globulus* in the category metabolic cellular process. In the *E. urophylla* X *E. grandis* comparison, the metabolic cellular process category is representative of the total number of contigs, however, the number of genes over-expressed in *E. urophylla* is much lower. This may be an indicative that genes that participate in such pathways can contribute to the differential wood qualities found in *E. globulus*.

The new assembly, RNAseq libraries and GBrowse are available at [www.lge.ibi.unicamp.br/eucalyptus](http://www.lge.ibi.unicamp.br/eucalyptus). *E. globulus* and *E. urophylla* libraries were compared against *E. grandis* library in order to access differentially expressed genes (considering 99% of confidence rate - cut-off of 0.01). As a result, 19,828 genes were differentially expressed in the *Egl X E. gr* comparison (51.43%) and 18,142 (49.27%) in *Eur X E. gr*. Also in these groups there were genes not expressed in one of the species, as can be seen in Venn diagram below (Figure 2). These results may contribute to the understanding of wood formation processes and possibly help guide its improvement. The increase in wood quality and productivity has significant economic impacts especially in the pulp and paper industry.

**References**

**Results:** A total of 479 proteins were identified in the proteome analysis of *C. acetobutylicum* from a single data point during the ABE fermentation process and 372 proteins were found to be present in both the first and second MS runs and identified as common proteins. This analysis confirms that 12 proteins were involved in the butanoate metabolism and about 32 uncharacterized proteins were found to be present during the ABE fermentation using glucose substrate. Overall, this is the first study which represents an extensive survey of whole proteome analysis of *C. acetobutylicum* from a single data point by multidimensional protein identification technology (MudPIT) and provides a valuable dataset of *C. acetobutylicum* proteins for a better understanding of the butanol production.

Using methylated DNA immunoprecipitation followed by high-throughput sequencing (MeDIP-seq), we analyzed DNA methylation patterns in the *P. trichocarpa* genome in relation to four biological processes: bud dormancy and release, mature organ maintenance, in vitro organogenesis, and methylation suppression. Here, we report results from Illumina sequencing of nine sampled tissues, each representing 1 to 2 biological replicates. We sequenced 26M – 97M reads per tissue type, and validated our MeDIP-seq results using bisulfite sequencing of selected targets. Unique MeDIP-seq reads covered ~30-60% of genome space at an average depth of 4 to 12 reads/nucleotide. Transposons and other repeat elements were enriched within the methylated fraction of the genome. The pattern of gene model methylation showed higher methylation at promoters, in the middle of coding regions, and 3’ to ends of genes, similar to that observed in other plant and animal species. Numbers of methylated genes identified varied widely by tissue type.

We produced summary data for genome methylation in *P. trichocarpa*, including the distribution of methylation across chromosomes (Fig. 1) and in and around genes. The intensity of methylation was highly heterogeneous within and between chromosomes. One-third of the genome, analyzed as 1 kb tiled windows, was differentially methylated among tissues. An example of a chromosomal region with differential methylation is shown in Fig. 2. Promoter methylation was more frequent than gene body methylation. Male catkins differed from the other tissues in that gene body methylation was more prevalent than promoter methylation, and two transposable element categories that were methylated in all other tissues were unmethylated in male catkins. We also analyzed the association of methylation intensity to gene expression data from an existing microarray study of the same tissues. At a whole genome scale, both promoter-
methylated and body-methylated genes had lower expression than unmethylated genes. We will report on our continued studies of tissue methylation/expression relationships.

We have developed a customized genome browser (GBrowse version 1.69), compatible with the most recent (v2.2.1) *P. trichocarpa* genome assembly, at which our data can be explored: http://poplar.cgrb.oregonstate.edu.

**BMC Proceedings** 2011, 5(Supp 7):P178

**Background:** Gmelina (*Gmelina arborea* Roxb), also known as white teak, is a tropical deciduous tree native from moist tropical forests of Asia. It has been successfully introduced in equatorial Africa, as well as central and south America. Gmelina is known for its very fast growing rate, its intrinsic disease, fire and drought tolerance, as well as the quality of its wood which is suitable for different types of uses such as paper pulpings, plywood or particle board industry, furniture and light constructions. In addition, gmelina is considered a pioneer species capable of rapidly colonizing eroded or low nutritional quality lands, which makes it interesting for reforestation or landscape restoration programs. Despite its ecological and increasing economic importance, very little is known about the biology of this species and its remarkable field behavior such as drought tolerance, at the genetic, molecular and biochemical levels.

Genomic tools have recently increased the numbers and volume of genomic resources for several crop plants and trees and have contributed to enlarge our knowledge on basic aspects of plant biology, population dynamics or phylogeny; furthermore, they represent valuable sources of candidate genes and new molecular markers to assist breeding programs. Biological sequences reported to date in public databases and belonging to Gmelina do not exceed 20 entries: this very narrow availability of genetic information is the main bottleneck to initiate molecular breeding programs in *Gmelina arborea*.

We report here the first genomic resource for this tropical tree based on an RNAseq transcriptome profiling approach.

**Methods:** Two subtracted cDNA libraries were constructed from both leaf and root tissue of gmelina seedlings submitted to a water deficit stress. Subtracted cDNA sequencing was completed using 454 GS FLX Titanium sequencing. After sequence trimming, de novo assembly and clustering were completed using TGICL assemblers and contigs were functionally annotated using BlastX against high quality curated protein reference databases. Both Gene Ontology (GO) terms and KEGG metabolic pathways assignments were used to further characterize transcripts. SSR motives were identified using MISA. Except for the KEGG pathway assignments, all the sequence analysis was compiled in the previously developed bioinformatic pipeline ESTTIK (http://esttik.cirad.fr/).

**Results:** A preliminary collection of 10,528 contigs and 10,661 singletons, enriched in drought related transcripts, was obtained from both root and leaf subtracted libraries. Contig sequence sizes ranged from 97 to 2.187 bp with an average of 456 bp and a mean coverage depth of 38-fold. Functional annotation was completed only for contigs: up to 65% of these assembled sequences had significant Blast hits and about half of all assembled contigs could be assigned to one or more GO terms (Table 1).

Top hit species for homology based annotations of gmelina unigenes were: *Arabidopsis thaliana* (20-27%), *Vitis vinifera* (10-14%), *Populus trichocarpa* (4-7%) and *Ricinus communis* (4-7%). Among the different biological processes, cellular and metabolic processes, biological regulation, localization and response to stimulus were the most highly represented GO term categories, involving several genes related to drought or general stress, transport, transcription regulation and signal transduction, as expected. Analysis of KEGG metabolic pathway assignments revealed that our gene catalog covers all major plant metabolic pathways, with a certain dominance of enzymes of the carbohydrate, amino acid and energy metabolism in leaves, indicative that those pathways, seemingly impaired in response to water deficit stress, tend to recover by means of an active transcriptional rate (Table 2). The metabolic response in roots was slightly different with dominance of enzymes related to lipid, amino acid and carbohydrate metabolism, supporting important membrane and osmotic adjustment mechanisms in these tissues. Importantly, our gene catalog comprises many genes encoding proteins involved in signal perception and transduction, effector proteins as well as proteins with regulatory functions, allowing to cover the whole molecular response to drought stress. On the other hand the presence of several unigenes with no blast hit or with homology to unknown hypothetical proteins opens the possibility to uncover either previously unknown or less characterized protein functions related to drought stress.

Finally, we also identified microsatellite motifs within 428 unigenes, from which, 255 primer pairs have been designed for further experimental validation as functional SSR markers.

**Conclusions:** In this survey, we present the first unigene resource of this economically important tropical timber for which almost no prior genetic information existed. We identified drought stress related genes in different functional categories ranging from membrane bound sensor proteins, signal transduction proteins, transcription factors to metabolic or effector proteins. The SSR motifs found are good candidates for drought-related functional marker development in this species. Altogether, the results represent a first contribution to a better knowledge of the biology of white teak as well as the molecular mechanisms underlying its drought tolerance, which is essential to further encourage breeding program developments.

BMC Proceedings 2011, 5(Suppl 7) P180

Background: Cryptomeria japonica D. Don (sugi) is one of the most important Japanese conifer species. Rapid improvement of the wood trait (e.g., growth speed and wood quality) using a conventional breeding approach is not possible, because breeding of coniferous trees requires a very long time. Genetic modification might be a powerful tool to shorten the time needed to breed trees compared with traditional breeding methods because it is able to induce the favorable traits by introduction of specific genes in trees without unnecessary genetic transitions. But the transfer of foreign genes from GM plants to related plant species by pollen has been cited as an environmental concern. For the purpose of creating male sterile GM C. japonica, we attempted to identify genes related to male flower formation.

Methods: To isolate the male strobilus specific genes, we constructed male strobilus specific SSH libraries based on three different stages according to male strobilus development: early stage, tetrad stage and mature stage. The microarray was designed using 19,259 genes consisting of isolated genes from SSH libraries and ForestGen(REST and GENome database [http://forestgen.ffpri.affrc.go.jp/en/index.html]). We analyzed expression profiling associated with male strobilus development. To isolate the male strobilus specific promoter of male strobilus specific genes, 1009-C47 and 1009-C96, TAIL-PCR methods were performed. To confirm the tissue specific activity of the promoter regions, the promoter:GUS fusions were introduced into Arabidopsis and C. japonica. Furthermore, we introduced 1009-C47::Barnase and 1009-C96::Barnase to Arabidopsis and C. japonica. We evaluated the ability of pollen formation of the transgenic Arabidopsis that introduced 1009-C47::Barnase and 1009-C96::Barnase construct.

Results and discussion: The microarray analysis was performed using cDNA of different developmental stages of male strobili: early stage, microspore mother cell stage, tetrad stage, free spore stage and mature pollen stage. We showed that the strongly expressed genes in each developmental stage were markedly different. The GUS assay revealed that the 1009-C47::GUS showed another specific GUS activity in Arabidopsis and C. japonica. The introduction of 1009-C47::Barnase and 1009-C96::Barnase into Arabidopsis led to male sterility phenotype. We showed probability that the 1009-C47 promoter and 1009-C96 promoter are useful for male sterilization of C. japonica.
Methodology: For the selection of the markers, a reference population of 30 unrelated parents for each species of interest (Eucalyptus globulus and Pinus radiata) was used. In these populations, we tested 25 SSR for pinus and 38 SSR for eucalyptus and the best 12 markers were selected for each species. With the selected markers, a pattern or fingerprint of each operational clone was obtained, out of samples taken from the original material (tree or embryogenic mass). Against these patterns, a total of over 20,000 samples were compared for validation of various operational processes. The sampling is planned to get 90% confidence of detecting operational errors (contamination) greater than 10%. Since the laboratory should process a large number of samples, protocols have been developed to be simple and short. DNA is extracted with 96 commercial Qiagen kit, for different tissues (embryogenic cells, embryos, leaves, bark, etc.). Sometimes, extractions are doubled by mixing leaf tissue of P. radiata and E. globulus, which is possible because SSRs amplified in one species do not interfere with the other. The amount of sample used for the extraction process varies from 50 to 200mg, which yields to concentrations of 30 to 100ng/ul of DNA. Since the amount is enough for several analyses, there is no need to store the original samples. The amplification is performed in thermal cyclers AB 9700 with a single PCR program for each species, using 10 ng of DNA for P. radiata and 2-4ng DNA for Eucalyptus sp. The reading of the fragments is performed in AB 3130xl Genetic Analyzer, while the analysis and correction of the electropherograms is done with the GeneMapper 4.0 program. The fingerprint comparison is made with self developed software, which reduces the noise of size variation observed between samples from the same clone and the appearance of false alleles or silent alleles. All these noises are more noticeable in some clone-marker combinations.

Results: Currently, Arauco has determined the pattern of 400 molecular clones of P. radiata and 200 clones of E. globulus. Thanks to the massive use of fingerprinting in the production and multiplication of clones, steps where mistakes are most likely have been identified and in many cases, errors have been repaired. During 2010, out of 4600 P. radiata samples corresponding to 170 clones, the rate of mistaken identity found was 5.6% in genetic field trials, 5.3% in the embryogenesis laboratory process and 8.4% in nurseries. In E. globulus for 3,000 samples analyzed, of 135 clones, the mistaken identity rate was found to be 7.4% in genetic field tests, 8.3% in clonal orchards and 7.1% in nursery samples.

Evaluating impact of possible transgenic poplar cultivation on protected areas

E-mail: donatella.paffetti@unifi.it

Background: Plant biodiversity studies have been performed in the Migliarino-San Rossore-Massaciuccoli Regional Park in Tuscany (Italy) within the framework of the European project LIFE08 NAT/IT/342.

Figure 1(abstract P182) Results of Geneland analyses of area A showing: (a) Spatial organisation into three clusters; (b), (c), and (d) are maps of posterior probabilities of each cluster.
This project aims at developing a quick monitoring index (QMI) to rapidly assess the potential risk generated by transgenic plants in characterized ecosystems or biotopes. For this reason test areas have been selected inside the protected area to evaluate plant (weeds and trees), animal, and soil microorganisms biodiversity. The proximity of the selected test area to cropped surfaces where Genetically Modified Plants (GMPs) might be cultivated has been taken into account. GMPs could spread pollen and contaminate natural populations. To avoid this risk, an efficient monitoring system is required taking into account genetic diversity and breeding functions.

Materials and methods: The selected Populus test areas are: A) a mixed forest stand in the Tenuta di San Rossore; B) a scattered Populus population in the wetland area of “lake of Massaciuccoli”. Test areas A and B are 8 Km apart.

Test area A is a naturally-originated mixed forest stand. The prevailing tree species are Populus alba, P. x canescens, Fraxinus angustifolia and Alnus glutinosa. In the test area B single trees and small groups of Populus spp. are scattered along the lake.

In the test area A an experimental subplot 2500 m² large has been designed and the position has been acquired by GPS. All Populus trees within the plot have been identified and their position have been collected by GPS. The stand structure analysis has been performed using spatial functions.

In the test area B the position of Populus has been acquired by GPS. The poplar populations present in areas were examined. From literature, six nuclear microsatellites were selected, all markers carried dinucleotides repeats except two with trinucleotides repeats [1,2].

Total DNA was extracted from the samples to perform microsatellite analysis [1,2]. Sizing of the PCR products was carried out using software Gene Mapper ver. 4.0 (Applied Biosystem).

In order to better define the species density and composition of the herbaceous stratum, some sampling subplots have been designed within the experimental plot by using the standardized multi-scale approach proposed by Dengler [3]. To define possible variations of distribution and/or density of plant species, their relative abundance has been evaluated according to the Braun Blanquet approach (1964).

During poplar tree blooming period inflorescences of male and female trees were collected. Weekly sampling was carried out with the aid of an elevator truck that permitted to collect samples out of reach.

Results: In relation to the herbaceous stratum, the observations made so far show some variability in the distribution of species to a plot to another, probably due to the micro topological characteristics of the site.

The biodiversity analysis of the insects present on poplar trees indicates an evident difference in the faunal community between male and female trees and a relatively low number of species. Dipteran larvae were most abundant followed by coleopterans such as coccinellids and curculionids, araneids and lepidopteran larvae.

The analysis of spatial and genetic structure of the two poplar populations was performed using Geneland [4]. The results of Geneland clearly showed that three distinct clusters can be identified in the area A (Figure 1a) indicating the presence gene flow barriers (Figures 1b, 1c, 1d). The cluster represented in Figure 1b comprise individuals with the same genotype as indicated by microsatellites data (not shown). In fact, it is highly probable that these individuals are root suckers. The second and third clusters show the occurrence of gene flow within and among the two clusters (Figures 1c and 1d). This indicates that a minor barrier is present because the other tree species of the stand block only in part the pollen flow. The same analysis indicates two clusters in area B (Figure 2) with a gene flow among them higher respect to the area A. In fact, this population is in an open area (lake) and therefore the pollen flow is favored.

Conclusions: In general the level of biodiversity within the selected test area is high, and in particular the level of gene flow inside area B. Therefore, the possible cultivation of transgenic poplar close to the protected areas could influence their biodiversity. Especially the level of gene flow can determine a contamination of the autochthon poplar populations. The development of a QMI using the experimental data is in course.
The availability of the QMI to rapidly assess the potential risk generated by transgenic plants in characterized ecosystems, is a useful tool to assess the releasing or not of the permission of cultivation close to protected areas.

Evaluation of different versions of the gene encoding green fluorescent protein (GFP) in plants

Camila B Scalco, Rochele P Kirch, Giancarlo Pasquali

Biotechnology Center, Federal University of Rio Grande do Sul, Porto Alegre, RS, Brazil

E-mail: camilascalco@gmail.com

BMC Proceedings 2011, 5(Suppl 7):P183

The main purpose of the "CDA Eucalyptus: Collaborating Center in Agriculture Defense Relative to the Biosafety of Genetically Modified (GM) Eucalyptus" is to gather, assess and validate the existing information concerning GM and non-GM Eucalyptus and its derivatives in the Brazilian environment; both in laboratories and field test experiments. Accordingly, the purpose of the present research activity is to provide a binary plasmid collection containing different versions of the gene encoding green fluorescent protein (GFP), originally from *Aequorea victoria*, for the future generation of easily detectable GM plant phenotypes. Using commercially available plasmids encoding blue (ECFP) and yellow (EYFP) versions of GFP for expression in bacteria, the initial strategy was to transfer the coding sequences to the intermediate plasmid pSPORT1 (Invitrogen) and, subsequently, to pART7 plasmid, which contains the promoter and terminator sequences for gene expression in plants. Although recombinant bacteria have been obtained for both genes, DNA sequencing showed that success was achieved only with pSPORT1-ecfp. So far, pART7 versions were not obtained. A new cloning strategy was proposed, which involves the binary plasmid pCAMBIA1302 (Cambia). This plasmid already contains one version of the gene for GFP expression in plants. The intention is to replace the *gfp* gene by ecfp, eYFP and mCherryFP versions. As soon as plasmids are finished, plants will be transformed via Agrobacterium tumefaciens, and their transgenic state will be confirmed by the fluorescence of the encoded proteins. Thus, the fluorescence of the GFP different versions will be used to monitor seeds, pollen, leaves and transgenic plants as a whole in the environment.

Plant biotechnology research at forest fields in South Korea

Jae In Park Chungbuk

National University, Korea

E-mail: jipark@chungbuk.ac.kr

BMC Proceedings 2011, 5(Suppl 7):P184

This paper is to give an outline of the tree biotechnology research in South Korea.

Tree Breeding, we call Traditional Tree Breeding later compared to Tree Biotechnology, started in 1954 in South Korea. Tree Biotechnology Research started as Tissue culture in the late 1970 in South Korea. Micropropagation was the first field adopted. Embryo culture, Bud culture, Callus culture, Cell culture are the methods for Micropropagation. Many tree species and herbaceous plants have been subjected to micropropagation and successfully established. Tall tree species, *Populus alba* x *P. glandulosa*, *Quercus*, *Betula et al* are successful for plantation, rare woody plants such as *Forsythia saxatilis*, *Abelium phylum disticum*, *Berchemia berheimeloflia*, *Hovenia dulis*, *Lagerstroemia indica* for. *alba*, *Emptim nigrum var. japonicum* were also subjected to in vitro culture. For somatic embryogenesis many species were successful in *Laxix leptolepis*, *Liriodendron tulipifera*, *Aralia elata*, and *Schisandra chinensis* et al. For Practical purpose a few species such as *Mountain ginseng* (root inductio from callus culture and subsequent root culture by liquid culture), thornless *Aralia elata* (somatic embryogenesis from petioles), *Leriodendron tulipifera* (somatic embryogenesis from immature zygotie embryo) are under way of commercialization. Mountain ginseng is wild ginseng grown in mountain area. In mountain area they live very long time , even as long as over 100 years meanwhile the plants of it can grow only up to 6 years and produce healthy secondary products for human body. After Multiplication the produced roots are utilized for liquor, cosmetics, medicines et al. Yellow poplar(*Liriodendron tulipifera*), introduced from north America, shows good growth performance and is planted widely throughout the country. Through mass propagation of superior trees by somatic embryogenesis clonal forestry is planned in the forest area.

Biosafety policy of south Korea is very strict. Cultivation of transformed plants is not allowed.

The following list shows the outline of the species which have been reported to be successful to the category in south Korea

**Bud culture;** *Populus alba* x *P. glandulosa*, *Kalopanax asepsoflos*, *Corylopsis coreana*, *Eucalyptus pelitita*, *Actinidia deliciosa* x *A. arguta*, *Prunus yedoensis*, *Dispyros kaki*. *Phellodendron amurese*, *Robinia pseudoacacia*, *Quercus acutissima*

**Forsythia koreana** for. aurorecticulata, *Salix hallasanensis*, *Sorbus commixta*, *Betula schmitti*, *Machilus thunbrugii*, *Aconitum koreanum*, *Juglans regia*, *Betula dahurica*, *Crataegus pinnatifida*, *Corylus avellana*, *Allanthus altissima*, *Medicago sativa*, *Lycium chinense*, *Robinia pseudoacacia* wild *Paxus ginseng*, *Populus koreana* x *P. nigra* var. *italica*, *Cotyledon culture;* *Pinus rigida* x *P. taeda*, *Cell culture;* *Salix koreensis*, *Gardeneda jasminoides*, *Tusax cuspidux*, *Hibiscus syriacus*, *Embryo culture;* *Pinus rigida* x *P. taeda*, *Camellia sinensis*, *Pimpinella brachycarpa*, *Populus glandulosa*, *Leaf culture;* *Camellia sinensis*, *Cambia tissue culture;* *Larix decidua*, *Somatic embryogenesis;* *Populus nigra* P. maxiovniczii, *Zyphus jubbua*, *Oplopanax elatus*, *Eleutherococcus koreanum*, *Kalopanax pictus*, *Aralia elata* "Zaoh", *Liriodendron tulipifera*, *Larix kaempferi*, *L. chinicum, Camellia sinensis, Oraostachys japonicus, Quercus variabilis*, *Pimpinella brachycarpa*, *Juglans regia*, *Anther culture;* *Populus glandulosa*, *Protoplast isolation or culture;* *Populus alba* x *P. glandulosa*, *Populus euramerican* *Populus alba*, *Populus glandulosa, P. nigra* P. maxiovniczii*, *Bioreactor culture;* *Ganoderma applanatum*, *Eleutherococcus koreanum*, *Tricholoma matsutake* (mycelium), *Lilium Casa Blanca*, *Acanthopanax sendicus*, *Acanthopanax koreanum*, *wild Panax ginseng*, *Molecular markers such as I-SSR marker, cpSSR marker have been developed in Quercus acutissima, Pinus densiflora, Salix koreensis* for forensic medicine

**Functional genomics;** *Populus alba* x *P. glandulosa*, *Magnolia kobus* **Quantitative Traits Loci for root growth;** *Populus davidiana*, *Root culture;* *Albizia kalkora*, *Eleutherococcus koreanum*, *Trisperumperum japonicum*, *Transformation;* *Populus alba* x *P. glandulosa* (Model tree), *Aralia elata*, *Populus koreana* x *P. nigra*, *Camellia chinensis*, *Populus nigra*, *Populus davidiana*, *Pinus densiflora*, *Quercus acutissima*, *I-SSR analysis;* Stewardia koreana, *Genus* *Gulor*, *Vaccinium uliginosum*, *Oplopanax elatus*, *Eleutherococcus senticosus*, *Ginkgo biloba*, *Abies holophylia*, *Torreya nucifera*, *Ginko biloba*, *Rhododendron schlippenbachii*, *Pinus densiflora*, *Tusax cuspidate*, *Thuja koreensis*, *Cryopreservation;* *Bursaphelenchus xylophilus* (Pine Wood Namatode), *Populus koreana* x *P. nigra* var. *italica*, *Populus alba* x *P. glandulosa* **Expressed Sequence Tags;** *Populus alba* x *P. tremula* var. *glandulosa*
COST Action FP0905: Biosafety of forest transgenic trees: improving the scientific basis for safe tree development and implementation of EU policy directives

Cristina Vettori1,* 1Plant Genetics Institute UOS FI – CNR, Via Madonna del Piano 10, 50019 Sesto Fiorentino FI, Italy; 2Johann Heinrich von Thuenen Institute (vTI), Institute for Forest Genetics, Sieker Landstr. 2, D-22927 Groshansdorf, Germany
E-mail: cristina.vettori@cnr.it
BMC Proceedings 2011, 5(Suppl 7):P185

Background: The potential for unintended consequences of the spread of foreign genes (either via vertical or horizontal transfer) and of pleiotropic effects following transgene expression may be enhanced in long-lived forest trees. The COST Action FP0905 will focus on four key aspects related to the biosafety of genetically modified trees (GMTs): (a) analyses of the efficiency of existing gene containment strategies to avoid or if not possible to minimize gene flow; (b) facilitate efforts to develop site-specific integration of transgenes in tree genomes to minimize variability of transgene expression and pleiotropic effects, (c) evaluate possible methods to monitor GMTs in the whole production chain, and (d) conduct socio-economic and cost/benefit analyses in relation to the use of GMTs in plantations.

This Action combines multidisciplinary knowledge generated with transgenic lines of different forest genera (such as, Populus spp., Pinus spp., Eucalyptus spp., Betula spp., Castanea spp., Picea spp., etc.) as well as extensive expertise in correlated topics. The information gained should contribute to strengthen the scientific basis for the execution of the EU policy directives related to transgenic trees intended for cultivation in Europe. The main objective of the COST Action is to evaluate and substantiate the scientific knowledge relevant for GMT biosafety protocols by putting together already existing information generated in various European and Non-EU countries as basis for future EU policy and regulation for the environmental impact assessment and the safe development and practical use of GMTs.

Work plan and organisation: To reach its aim, the work plan of the Action is organised in 4 Working Groups (WGs) to implement collaboration of scientists.

WG 1 - Biological characterization of GMTs: to characterize the GMTs in respect to their genetic and phenotypic features relevant for gene flow, gene containment and gene targeting.

WG 2 - Environmental impact assessment and monitoring of GMTs in the whole production chain from plantation to final products: to study environmental risk assessment strategies and monitoring the GMTs along the whole production chain.

WG 3 - Socio-economic implications of and recommendations for the use of GMTs: to make socio-economics analyses of the use of GMTs considering the concerns and acceptance by the public, the economic potential for GMTs and R&D efforts to be invested, as well as cost/benefit analyses, and propose recommendations for the use of GMTs.

WG 4 - Management of intranet - internet websites and dissemination: through a website (www.cost-action-fp0905.eu), provide science-based information and increase public awareness in the utilization of GMTs in forest plantation and at the same time safeguarding the environment.

The knowledge gained will be summarised in a book as a final output of this Action which will report the state of art of knowledge and research on GMTs with suggestion on how to effectively implement present EU directives on GMO considering the problematic of forest trees and their environmental impacts.

The Action started the 12th of April 2010 and it will end the 11th of April 2014. Actually, 23 COST countries (Austria, Belgium, Bosnia and Herzegovina, Bulgaria, Croatia, Denmark, Estonia, Finland, France, Germany, Greece, Israel, Italy, Latvia, Netherlands, Norway, Romania, Serbia, Slovak Republic, Slovenia, Spain, Sweden, and United Kingdom) have signed the Memorandum of Understanding (MoU). Seven NON-COST countries (Albania, Australia, Canada, China, New Zealand, South Africa, USA) are participating to the Action.

Conclusion: With integration of all the countries listed above, the EU COST Action FP0905 is expected to generate important benefits as it also foresees a strong collaboration among R&D bodies and legislative directives. This kind of collaboration will be fundamental, on the one hand, to address policy-making efforts and, on the other hand, to allow the scientific community to discuss to public concerns in a responsible way, particularly concerning socio-economic implications and biosafety issues of transgenic tree plantations.
